Sex hormones—Hormones that are responsible for sexual characteristics and reproductive functioning.

Steroids—A class of hormones and drugs that includes sex and stress hormones and anti-inflammatory medications, contraceptives, and growth-promoting substances.

Sterols—Steroid alcohols, such as cholesterol, that are widely distributed in the body.

Testosterone—The primary male sex hormone.

to support this and cycling may build tolerance, requiring higher dosages.

Precautions

Although AASs are considered to be relatively safe at the usual prescribed dosages, at abusive dosages they can result in a wide range of serious health problems, including:

- abnormal lipid profiles
- early heart attacks
- strokes
- kidney failure
- severe liver problems including jaundice, tumors, and cancer
- depression
- severe psychiatric disturbances

Unsafe injection of AASs can result in HIV and **hepatitis B** and C infections. It also has been suggested that steroids may be gateway drugs for **narcotics** abuse and it is possible to become psychologically addicted to them.

Withdrawal from high doses of AASs may require:

- medication to relieve withdrawal symptoms
- antidepressants
- hormones to restore normal hormonal function

Pediatric

AASs should be used with extreme caution in children. They can cause early **puberty** and lead to premature cessation of bone growth, resulting in permanent short stature.

A 2008 survey found that 1.4% of eighth graders, 1.4% of tenth graders, and 2.2% of twelfth graders had used AASs. Some were athletes attempting to increase their strength and size; others were simply attempting to speed up their growth to keep pace with their peers. Many teenagers also are attracted by the psychological rush that comes with steroid abuse. Prevention programs often target school- or community-sponsored athletic teams, coaches, and team leaders. It has been recommended that educational prevention programs start with middle-school athletes.

Geriatric

Elderly patients can be more sensitive to the effects of AASs. They should not be used in elderly people with prostate problems, fluid buildup, or abnormal liver function.

Pregnant or breastfeeding

Pregnant women or women who are planning to become pregnant should never take AASs because they are known to cause **birth defects**. Although it is not known whether most AASs pass into breast milk, lactating women should avoid these drugs.

Other conditions and allergies

People with the following conditions should never take an AAS:

- high blood calcium levels (hypercalcemia)
- prostate cancer
- breast cancer in males
- breast cancer with high calcium levels in females
- severe kidney damage

The following conditions may be contraindications for AASs:

- heart or blood vessel disease
- previous heart attack
- high blood cholesterol
- bleeding or clotting problems
- diabetes, since AASs can affect blood sugar levels
- liver or kidney problems

Side effects

AASs usually have few side effects at medical dosages. However at the much higher doses used to improve **body image** or athletic performance, side effects can be serious and sometimes irreversible. Excessive use can cause harmful imbalances in hormones and body chemistry.

Common side effects of AASs include:

- excitability
- changes in sex drive
- swelling of the feet and ankles
- baldness
- breast swelling
- change in skin color
- diarrhea
- nausea
- vomiting
- insomnia
- bladder irritation
- fertility problems
- testicular problems
- difficulty achieving an erection

WWW.BOOKBAZ.IR

Rare but more severe side effects of medically prescribed dosages of AASs include:

- severe allergic reactions
- acne, especially in women
- darkened urine
- deepening of the voice in women
- increased facial and body hair in women
- menstrual changes
- frequent painful erections
- behavioral or emotional changes
- jaundice

Side effects of AAS abuse can include:

- shrinking testicles, falling sperm counts, gynecomastia (swelling and enlargement of the breasts), increased urination, and enlarged prostate glands in males
- virilization in females, including hirsutism (growth of body and facial hair), male-pattern baldness, cessation of menstruation, decreased breast size, deepening of the voice, and abnormal enlargement of the clitoris
- an increase in "bad" cholesterol (LDL) and a decrease in "good" cholesterol (HDL)
- water retention leading to high blood pressure and stroke
- heart attacks
- liver and kidney tumors
- insomnia
- drastic mood swings ranging from mania to depression
- aggression, paranoia, irritability, delusions, hostility, psychosis

Pediatric

Side effects of AASs in young people can include:

- acne
- early puberty
- an initial growth spurt
- premature cessation of growth due to closure of growth plates

Other conditions and allergies

AAS preparations can contain various ingredients that may cause allergic reactions in some people.

Interactions

AASs may interact with:

- anticoagulants such as warfarin (Coumadin)
- carbamazepine
- insulin or oral diabetes medications
- corticosteroids
- eucaplyptus
- kava (*Piper methysticum*)

Stillbirth

Definition

A stillbirth is defined as the death of a fetus at any time after the twentieth week of **pregnancy**. Stillbirth is also referred to as intrauterine fetal death (IUFD).

Description

It is important to distinguish between a *stillbirth* and other words that describe the unintentional end of a pregnancy. A pregnancy that ends before the twentieth week is called a **miscarriage** rather than a stillbirth, even though the death of the fetus is a common cause of miscarriage. After the twentieth week, the unintended end of a pregnancy is called a stillbirth if the infant is dead at birth.

Factors that increase a mother's risk of stillbirth include: age over 35, **malnutrition**, inadequate prenatal care, **smoking**, and alcohol or drug abuse.

Causes and symptoms

Causes

A number of different disorders can cause stillbirth. They include:

- Pre-eclampsia and eclampsia. These are disorders of late pregnancy characterized by high blood pressure, fluid retention, and protein in the urine.
- Diabetes in the mother.
- Hemorrhage.
- Abnormalities in the fetus caused by infectious diseases, including syphilis, toxoplasmosis, German measles (rubella), and influenza.
- Severe birth defects, including spina bifida. Birth defects are responsible for about 20% of stillbirths.
- Postmaturity. Postmaturity is a condition in which the pregnancy has lasted 41 weeks or longer.
- Unknown causes. These account for about one-third of stillbirths.

Symptoms

In most cases the only symptom of stillbirth is that the mother notices that the baby has stopped moving. In some cases, the first sign of fetal death is **premature labor**. Premature labor is marked by a rush of fluid from the vagina, caused by the tearing of the membrane around the baby; and by abdominal cramps or contractions.

KEY TERMS

Alpha-fetoprotein analysis—A blood test that can be done after the sixteenth week of pregnancy to evaluate the possibility of spina bifida and other birth defects in the fetus.

Electronic fetal nonstress test—A test in which electronic monitors attached to the mother's abdomen to detect contractions of the uterus as well as the baby's heartbeat and movements.

Miscarriage—The spontaneous end of a pregnancy before the twentieth week. The death of the fetus is a common cause of miscarriage.

Oxytocin—A drug that is given to induce labor in some cases of stillbirth.

Pre-eclampsia and eclampsia—Disorders of late pregnancy associated with high blood pressure, fluid retention, and protein in the urine. They can cause stillbirth.

Premature delivery—The birth of a live baby when a pregnancy ends spontaneously after the twentieth week.

Diagnosis

When the mother notices that fetal movement has stopped, the doctor can use several techniques to evaluate whether the baby has died. The doctor can listen for the fetal heartbeat with a stethoscope, use Doppler **ultrasound** to detect the heartbeat, or give the mother an electronic fetal nonstress test. In this test, the mother lies on her back with electronic monitors attached to her abdomen. The monitors record the baby's heart rate, movements, and contractions of the uterus.

Treatment

Medical

In most cases of intrauterine death, the mother will go into labor within two weeks of the baby's death. If the mother does not go into labor, the doctor will bring on (induce) labor in order to prevent the risk of hemorrhage. Labor is usually induced by giving the mother a drug (oxytocin) that cause the uterus to contract.

Follow-up therapy

Emotional support from family and friends, self-help groups, and counseling by a mental health professional can help bereaved parents cope with their loss.

WWW.BOOKBAZ.IR

Prognosis

With the exception of women with diabetes, women who have a stillbirth have as good a chance of carrying a future pregnancy to term as women who are pregnant for the first time.

Prevention

The risk of stillbirth can be lowered to some extent by good prenatal care and the mother's avoidance of exposure to infectious diseases, smoking, alcohol abuse, or drug consumption. Tests before delivery (**antepartum testing**), such as ultrasound, the alpha-fetoprotein blood test, and the electronic fetal non-stress test, can be used to evaluate the health of the fetus before there is a stillbirth.

Stockholm syndrome

Definition

Stockholm syndrome refers to a group of psychological symptoms that occur in some persons in a captive or hostage situation. It has received considerable media publicity in recent years because it has been used to explain the behavior of such well-known kidnapping victims as Patty Hearst (1974) and Elizabeth Smart (2002). The term takes its name from a bank robbery in Stockholm, Sweden, in August 1973. The robber took four employees of the bank (three women and one man) into the vault with him and kept them hostage for 131 hours. After the employees were finally released, they appeared to have formed a paradoxical emotional bond with their captor; they told reporters that they saw the police as their enemy rather than the bank robber and that they had positive feelings toward the criminal. The syndrome was first named by Nils Bejerot (1921–1988), a medical professor who specialized in **addiction** research and served as a psychiatric consultant to the Swedish police during the standoff at the bank. Stockholm syndrome is also known as Survival Identification Syndrome.

Description

Stockholm syndrome is considered a complex reaction to a frightening situation and experts do not agree completely on all of its characteristic features or on the factors that make some people more susceptible than others to developing it. One reason for the disagreement is that it would be unethical to test theories about the syndrome by experimenting on human beings. The data for understanding the syndrome are derived from actual hostage situations since 1973 that differ considerably from one another in terms of location, number of people involved, and time frame. Another source of disagreement concerns the extent to which the syndrome can be used to explain other historical phenomena or more commonplace types of abusive relationships. Many researchers believe that Stockholm syndrome helps to explain certain behaviors of survivors of World War II concentration camps; members of religious cults; battered wives; incest survivors; and physically or emotionally abused children as well as persons taken hostage by criminals or terrorists.

Most experts, however, agree that Stockholm syndrome has three central characteristics:

- The hostages have negative feelings about the police or other authorities.
- The hostages have positive feelings toward their captor(s).
- The captors develop positive feelings toward the hostages.

Causes & symptoms

Stockholm syndrome does not affect all hostages (or persons in comparable situations); in fact, a Federal Bureau of Investigation (FBI) study of over 1200

hostage-taking incidents found that 92% of the hostages did *not* develop Stockholm syndrome. FBI researchers then interviewed flight attendants who had been taken hostage during airplane hijackings, and concluded that three factors are necessary for the syndrome to develop:

- The crisis situation lasts for several days or longer.
- The hostage takers remain in contact with the hostages; that is, the hostages are not placed in a separate room.
- The hostage takers show some kindness toward the hostages or at least refrain from harming them. Hostages abused by captors typically feel anger toward them and do not usually develop the syndrome.

In addition, people who often feel helpless in other stressful life situations or are willing to do anything in order to survive seem to be more susceptible to developing Stockholm syndrome if they are taken hostage.

People with Stockholm syndrome report the same symptoms as those diagnosed with **post-traumatic stress disorder** (PTSD): **insomnia**, nightmares, general irritability, difficulty concentrating, being easily startled, feelings of unreality or confusion, inability to enjoy previously pleasurable experiences, increased distrust of others, and flashbacks.

Diagnosis

Stockholm syndrome is a descriptive term for a pattern of coping with a traumatic situation rather than a diagnostic category. Most psychiatrists would use the diagnostic criteria for **acute stress disorder** or posttraumatic **stress** disorder when evaluating a person with Stockholm syndrome.

Treatment

Treatment of Stockholm syndrome is the same as for PTSD, most commonly a combination of medications for short-term sleep disturbances and **psychotherapy** for the longer-term symptoms.

Prognosis

The prognosis for recovery from Stockholm syndrome is generally good, but the length of treatment needed depends on several variables. These include the nature of the hostage situation; the length of time the crisis lasted, and the individual patient's general coping style and previous experience(s) of **trauma**.

KEY TERMS

Coping—In psychology, a term that refers to a person's patterns of response to stress. Some patterns of coping may lower a person's risk of developing Stockholm syndrome in a hostage situation.

Flashback—The re-emergence of a traumatic memory as a vivid recollection of sounds, images, and sensations associated with the trauma. Persons having the flashback typically feel as if they are reliving the event. Flashbacks were first described by doctors treating combat veterans of World War I (1914–1918).

Identification with an aggressor—In psychology, an unconscious process in which a person adopts the perspective or behavior patterns of a captor or abuser. Some researchers consider it a partial explanation of Stockholm syndrome.

Regression—In psychology, a return to earlier, usually childish or infantile, patterns of thought or behavior.

Syndrome—A set of symptoms that occur together.

Prevention

Prevention of Stockholm syndrome at the level of the larger society includes further development of crisis intervention skills on the part of law enforcement as well as strategies to prevent kidnapping or hostage-taking incidents in the first place. Prevention at the individual level is difficult because researchers have not been able to identify all the factors that may place some persons at greater risk than others; in addition, they disagree on the specific psychological mechanisms involved in Stockholm syndrome. Some regard the syndrome as a form of regression (return to childish patterns of thought or action) while others explain it in terms of emotional **paralysis** ("frozen fright") or identification with the aggressor.

Stomach cancer

Definition

Stomach cancer (also known as gastric cancer) is a disease in which the cells forming the inner lining of the stomach become abnormal and start to divide uncontrollably, forming a mass called a tumor.

Description

The stomach is a J-shaped organ that lies in the left and central portion of the abdomen. The stomach produces many digestive juices and acids that mix with food and aid in the process of digestion. There are five regions of the stomach that doctors refer to when determining the origin of stomach cancer. These are:

- the cardia, area surrounding the cardiac sphincter which controls movement of food from the esophagus into the stomach,
- the fundus, upper expanded area adjacent to the cardiac region,
- the antrum, lower region of the stomach where it begins to narrow,
- the prepyloric, region just before or nearest the pylorus,
- and the pylorus, the terminal region where the stomach joins the small intestine

Cancer can develop in any of the five sections of the stomach. Symptoms and outcomes of the disease will vary depending on the location of the cancer.

Based on previous data from the National Cancer Institute and the United States Census, the American Cancer Society estimates that 24,590 Americans will be diagnosed with stomach cancer during 2015 and approximately 10,720 deaths will result from the disease. In most areas, men are affected by stomach cancer nearly twice as often as women. Most cases of stomach cancer are diagnosed between the ages of 50 and 70, but in families with a hereditary risk of stomach cancer, younger cases are more frequently seen.

Stomach cancer is one of the leading causes of cancer deaths in several areas of the world, most notably Japan and other Asian countries. In Japan it

appears almost ten times as frequently as in the United States. The number of new stomach cancer cases is decreasing in some areas, however, especially in developed countries. In the United States, incidence rates have dropped from 30 individuals per 100,000 in the 1930s, to only 8 in 100,000 individuals developing stomach cancer by the 1980s. The use of refrigerated foods and increased consumption of fresh fruits and vegetables, instead of preserved foods with high salt content, may be a reason for the decline.

Causes and symptoms

While the exact cause for stomach cancer has not been identified, several potential factors have lead to increased numbers of individuals developing the disease and therefore, significant risk has been associated. Diet, work environment, exposure to the bacterium *Helicobacter pylori*, and a history of stomach disorders, such as **ulcers** or polyps, are some of these believed causes.

Studies have shown that eating foods with high quantities of salt and nitrites increases the risk of stomach cancer. The diet in a specific region can have a great impact on its residents. Making changes to the types of foods consumed has been shown to decrease likelihood of disease, even for individuals from countries with higher risk. For example, Japanese people who move to the United States or Europe and change the types of foods they eat have a far lower chance of developing the disease than do Japanese people who remain in Japan and do not change their dietary habits. Eating recommended amounts of fruit and vegetables may lower a person's chances of developing this cancer.

A high risk for developing stomach cancers has been linked to certain industries as well. The best proven association is between stomach cancer and persons who work in coal mining and those who work processing timber, nickel, and rubber. An unusually large number of these workers have been diagnosed with this form of cancer.

Several studies have identified a bacterium (*Helicobacter pylori*) that causes stomach ulcers (inflammation in the inner lining of the stomach). Chronic (long-term) infection of the stomach with these bacteria may lead to a particular type of cancer (lymphomas or mucosa-associated lymphoid tissue [MALT]) in the stomach.

Another risk factor is the development of polyps, benign growths in the lining of the stomach. Although polyps are not cancerous, some may have the potential to turn cancerous. People in blood group A are also at elevated risk for this cancer for unknown reasons. Other speculative causes of stomach cancer include previous stomach surgery for ulcers or other conditions, or a form of anemia known as **pernicious anemia**.

Stomach cancer is a slow-growing cancer. It may be years before the tumor grows very large and produces distinct symptoms. In the early stages of the disease, the patient may only have mild discomfort, **indigestion**, **heartburn**, a bloated feeling after eating, and mild nausea. In the advanced stages, a patient will have loss of appetite and resultant weight loss, stomach pains, **vomiting**, difficulty in swallowing, and blood in the stool. Stomach cancer often spreads (metastasizes) to adjoining organs such as the esophagus, adjacent lymph nodes, liver, or colon.

Diagnosis

Unfortunately, many patients diagnosed with stomach cancer experience **pain** for two or three years before informing a doctor of their symptoms. When a doctor suspects stomach cancer from the symptoms described by the patient, a complete medical history will be taken to check for any risk factors. A thorough **physical examination** will be conducted to assess all the symptoms. Laboratory tests may be ordered to check for blood in the stool (**fecal occult blood test**) and anemia (low red blood cell count), which often accompany gastric cancer.

In some countries, such as Japan, it is appropriate for patients to be given routine screening examinations for stomach cancer, as the risk of developing cancer in that society is very high. Such screening might be useful for all high-risk populations. Due to the low prevalence of stomach cancer in the United States, routine screening is usually not recommended unless a family history of the disease exists.

Whether as a screening test or because a doctor suspects a patient may have symptoms of stomach cancer, **endoscopy** or barium x rays are used in diagnosing stomach cancer. For a barium x ray of the upper gastrointestinal tract, the patient is given a chalky, white solution of barium sulfate to drink. This solution coats the esophagus, the stomach, and the small intestine. Air may be pumped into the stomach after the barium solution in order to get a clearer picture. Multiple x rays are then taken. The barium coating helps to identify any abnormalities in the lining of the stomach.

In another more frequently used test, known as upper gastrointestinal endoscopy, a thin, flexible, lighted tube (endoscope) is passed down the patient's

WWW.BOOKBAZ.IR

throat and into the stomach. The doctor can view the lining of the esophagus and the stomach through the tube. Sometimes, a small **ultrasound** probe is attached at the end of the endoscope. This probe sends high frequency sound waves that bounce off the stomach wall. A computer creates an image of the stomach wall by translating the pattern of echoes generated by the reflected sound waves. This procedure is known as an **endoscopic ultrasound** or EUS.

Endoscopy has several advantages, in that the physician is able to see any abnormalities directly. In addition, if any suspicious-looking patches are seen, biopsy forceps can be passed painlessly through the tube to collect some tissue for microscopic examination. This is known as a biopsy. EUS is beneficial because it can provide valuable information on depth of tumor invasion.

After stomach cancer has been diagnosed and before treatment starts, another type of x-ray scan is taken. Computed tomography (CT) is an imaging procedure that produces a three-dimensional picture of organs or structures inside the body. CT scans are used to obtain additional information in regard to how large the tumor is and what parts of the stomach it borders; whether the cancer has spread to the lymph nodes; and whether it has spread to distant parts of the body (metastasized), such as the liver, lung, or bone. A CT scan of the chest, abdomen, and pelvis is taken. If the tumor has gone through the wall of the stomach and extends to the liver, pancreas, or spleen, the CT will often show this. Although a CT scan is an effective way of evaluating whether cancer has spread to some of the lymph nodes, it is less effective than EUS in evaluating whether the nodes closest to the stomach are free of cancer. However, CT scans, like barium x rays, have the advantage of being less invasive than upper endoscopy.

Laparoscopy is another procedure used to stage some patients with stomach cancer. This involves a medical device similar to an endoscope. A laparoscopy is a **minimally invasive surgery** technique with one or a few small incisions, which can be performed on an outpatient basis, followed by rapid recovery. Patients who may receive **radiation therapy** or **chemotherapy** before surgery may undergo a laparoscopic procedure to determine the precise stage of cancer. The patient with bone pain or with certain laboratory results should be given a **bone scan**.

Benign gastric neoplasms are tumors of the stomach that cause no major harm. One of the most common is called a submucosal leiomyoma. If a leiomyoma starts to bleed, surgery should be performed to remove it. However, many leiomyomas require no treatment. Diagnosis of stomach cancers should be conducted carefully so that if the tumor does not require treatment the patient is not subjected to a surgical operation.

Treatment

More than 95% of stomach cancers are caused by adenocarcinomas, malignant cancers that originate in glandular tissues. The remaining 5% of stomach cancers include lymphomas and other types of cancers. It is important that gastric lymphomas be accurately diagnosed because these cancers have a much better prognosis than stomach adenocarcinomas. Approximately half of the people with gastric lymphomas survive five years after diagnosis. Treatment for gastric lymphoma involves surgery combined with chemotherapy and radiation therapy.

Staging of stomach cancer is based on how deep the growth has penetrated the stomach lining; to what extent (if any) it has invaded surrounding lymph nodes; and to what extent (if any) it has spread to distant parts of the body (metastasized). The more confined the cancer, the better the chance for a cure.

One important factor in the staging of adenocarcinoma of the stomach is whether or not the tumor has invaded the surrounding tissue and, if it has, how deep it has penetrated. If invasion is limited, prognosis is favorable. Disease tissue that is more localized improves the outcome of surgical procedures performed to remove the diseased area of the stomach. This is called a resection of the stomach.

Several distinct ways of classifying stomach cancer according to cell type have been proposed. The Lauren classification is encountered most frequently. According to this classification system, gastric adenocarcinomas are either called intestinal or diffuse. Intestinal cancers are much like a type of intestinal cancer called intestinal carcinoma. Intestinal tumors are more frequently found in males and in older patients. The prognosis for these tumors is better than that for diffuse tumors. Diffuse tumors are more likely to infiltrate, that is, to move into another organ of the body.

Because symptoms of stomach cancer are so mild, treatment often does not commence until the disease is well advanced. The three standard modes of treatment for stomach cancer include surgery, radiation therapy, and chemotherapy. While deciding on the patient's treatment plan, the doctor takes into account many factors. The location of the cancer and its stage are important considerations. In addition, the patient's age, general health status, and personal preferences are also taken into account.

Surgery

In the early stages of stomach cancer, surgery may be used to remove the cancer. Surgical removal of adenocarcinoma is the only treatment capable of eliminating the disease. Laparoscopy is often used before surgery to investigate whether or not the tumor can be removed surgically. If the cancer is widespread and cannot be removed with surgery, an attempt will be made to remove blockage and control symptoms such as pain or bleeding. Depending on the location of the cancer, a portion of the stomach may be removed, a procedure called a partial **gastrectomy**. In a surgical procedure known as total gastrectomy, the entire stomach may be removed. However, doctors prefer to leave at least part of the stomach if possible. Patients who have been given a partial gastrectomy achieve a better quality of life than those having a total gastrectomy and typically lead normal lives. Even when the entire stomach is removed, the patients quickly adjust to a different eating schedule. This involves eating small quantities of food more frequently. High-protein foods are generally recommended.

Partial or total gastrectomy is often accompanied by other surgical procedures. Lymph nodes are frequently removed and nearby organs, or parts of these organs, may be removed if cancer has spread to them. Such organs may include the pancreas, colon, or spleen.

Preliminary studies suggest that patients who have tumors that cannot be removed by surgery at the start of therapy may become candidates for surgery later. Combinations of chemotherapy and radiation therapy are sometimes able to reduce disease for which surgery is not initially appropriate. Preliminary studies are being performed to determine if some of these patients can become candidates for surgical procedures after such therapies are applied.

Chemotherapy

Whether or not patients undergoing surgery for stomach cancer should receive chemotherapy is a controversial issue. Chemotherapy involves administering anti-cancer drugs either intravenously (through a vein in the arm) or orally (in the form of pills). This can either be used as the primary mode of treatment or after surgery to destroy any cancerous cells that may have migrated to distant sites. Most cancers of the gastrointestinal tract do not respond well to chemotherapy, however, adenocarcinoma of the stomach and advanced stages of cancer are exceptions.

Chemotherapy medicines such as doxorubicin, mitomycin C, and 5-fluorouracil, used alone, provide benefit to at least one in five patients. Combinations of agents may provide even more benefit, although it is not certain that this includes longer survival. For example, some doctors use what is called the FAM regimen, which combines 5-fluorouacil, doxorubicin, and mitomycin. Some doctors prefer using 5-fluorouracil alone to FAM since side effects are more moderate. Another combination some doctors are using involve high doses of the medications methotrexate, 5-fluorouracil, and doxorubicin. Other combinations that have shown benefit include the ELF regimen, a combination of leucovorin, 5-fluorouracil, and etoposide. The EAP regimen, a combination of etoposide, doxorubicin, and cisplatin is also used.

Although chemotherapy using a single medicine is sometimes used, the best response rates are often achieved with combinations of medicines. Therefore, in addition to studies exploring the effectiveness of new medicines there are other studies attempting to evaluate how to best combine existing forms of chemotherapy to bring the greatest degree of help to patients.

Radiation therapy

Radiation therapy is often used after surgery to destroy the cancer cells that may not have been completely removed during surgery. To treat stomach cancer, external beam radiation therapy is generally used. In this procedure, high-energy rays from a machine that is outside of the body are concentrated on the area of the tumor. In the advanced stages of gastric cancer, radiation therapy is used to ease symptoms such as pain and bleeding. However, studies of radiation treatment for stomach cancer have shown that the way it has been used it has been ineffective for many patients.

Researchers are actively assessing the role of chemotherapy and radiation therapy used before a surgical procedure is conducted. They are searching for ways to use both chemotherapy and radiation therapy so that they increase the length of survival of patients more effectively than current methods are able to do.

Prognosis

Overall, approximately 20% of patients with stomach cancer live at least five years following diagnosis. Patients diagnosed with stomach cancer in its early stages have a far better prognosis than those for whom it is in the later stages. In the early stages, the tumor is small, lymph nodes are unaffected, and the cancer has not migrated to the lungs or the liver. Unfortunately, only about 20% of patients with stomach cancer are diagnosed before the cancer had spread to the lymph nodes or formed a distant metastasis.

KEY TERMS

Adenocarcinoma—Malignant cancers that originate in the tissues of glands or that form glandular structures.

Anemia—A condition in which iron levels in the blood are low.

Barium x ray (upper GI)—An x-ray test of the upper part of the gastrointestinal (GI) tract (including the esophagus, stomach, and a small portion of the small intestine) after the patient is given a white, chalky barium sulfate solution to drink. This substance coats the upper GI and the x rays reveal any abnormality in the lining of the stomach and the upper GI.

Biopsy—Removal of a tissue sample for examination under the microscope to check for cancer cells.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Endoscopic ultrasound (EUS)—A medical procedure in which sound waves are sent to the stomach wall by an ultrasound probe attached to the end of an endoscope. The pattern of echoes generated by the reflected sound waves are translated into an image of the stomach wall by a computer.

External radiation therapy—Radiation therapy that focuses high-energy rays from a machine on the area of the tumor.

Infiltrate—To move into another organ of the body.

Polyp—An abnormal growth that develops on the inside of a hollow organ such as the colon, stomach, or nose.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Total gastrectomy—Surgical removal (excision) of the entire stomach.

Upper endoscopy—A medical procedure in which a thin, lighted, flexible tube (endoscope) is inserted down the patient's throat. Through this tube the doctor can view the lining of the esophagus, stomach, and the upper part of the small intestine.

It is important to remember that statistics on prognosis may be misleading. Newer therapies are being developed rapidly and five-year survival has not yet been measured with these. Also, the largest group of people diagnosed with stomach cancer are between 60 and 70 years of age, suggesting that some of these patients die not from cancer but from other age-related diseases. As a result, some patients with stomach cancer may be expected to have longer survival than did patients just ten years ago.

Prevention

Avoiding many of the risk factors associated with stomach cancer may prevent its development. Excessive amounts of salted, smoked, and pickled foods should be avoided, as should foods high in nitrates. A diet that includes recommended amounts of fruits and vegetables is believed to lower the risk of several cancers, including stomach cancer. The American Cancer Society recommends eating at least five servings of fruits and vegetables daily and choosing six servings of food from other plant sources, such as grains, pasta, beans, cereals, and whole grain bread.

Abstaining from tobacco and excessive amounts of alcohol will reduce the risk for many cancers. In countries where stomach cancer is common, such as Japan, early detection is important for successful treatment.

Stomach flushing

Definition

Stomach flushing is the repeated introduction of fluids into the stomach through a **nasogastric tube**, and their subsequent withdrawal by nasogastric suction.

Purpose

Stomach flushing is performed to aid in controlling gastrointestinal bleeding or to cleanse the stomach of poisons.

Controlling stomach bleeding

Bleeding from the esophagus due to ruptured veins or bleeding from the stomach due to **ulcers** is a medical emergency. In an attempt to stop the bleeding, the stomach is flushed with large quantities of body-temperature saline solution or ice water. This procedure is called stomach flushing or gastric lavage.

Stomach flushing to control bleeding is not uniformly accepted, and some experts believe it is of little benefit and exposes the patient to unnecessary risks. It is usually done in conjunction with the administration of drugs to constrict the blood vessels.

Stomach flushing to remove poisons

At one time, stomach flushing was common practice to remove certain poisons. Recent thinking by the American Academy of Clinical Toxicology is that stomach flushing should not be used routinely with poisoned patients. It is useful only if the patient has swallowed a life-threatening quantity of poison, and when the flushing can be done within 60 minutes of having swallowed the poison.

Precautions

In **poisoning** cases, stomach flushing should not be used if the poison is a strong corrosive acid (hydrochloric acid, sulfuric acid), alkali (lye, ammonia), or a volatile hydrocarbon such as gasoline. Stomach flushing should also not be done on patients who are having convulsions. Patients who are losing or have lost consciousness must have their airways intubated before a nasogastric tube is inserted.

Description

Stomach flushing is performed in a hospital emergency room or intensive care unit by an emergency room physician or gastroenterologist. A nasogastric tube is inserted, and small amounts of saline or ice water are introduced into the stomach and withdrawn. The procedure is repeated until the withdrawn fluid is clear.

KEY TERMS

Electrolytes—Salts and minerals that ionize in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost any major biochemical reaction in the body.

Saline solution—A salt water solution that mimics the concentration of electrolytes in the blood.

Preparation

Little preparation is necessary for this procedure other than educating the patient as to what will happen. The patient should remove dental appliances before the nasogastric tube is inserted.

Aftercare

After stomach flushing, the patient's vital signs will be monitored. Checks will be made for fluid and electrolyte imbalances. If necessary, additional treatment to prevent gastrointestinal bleeding or poisoning will be done.

Risks

In poisoning cases, stomach flushing delays the administration of **activated charcoal**, which may be more beneficial to treating the patient than flushing the stomach. In addition, stomach flushing may stimulate bleeding from the esophagus or stomach. The patient may inhale some of the stomach contents, causing aspiration, **pneumonia**, or infection in the lungs. Fluid and electrolyte imbalances are more likely to occur in older, sicker patients. Mechanical damage to the throat is more likely in patients who are uncooperative.

Results

Stomach flushing is usually tolerated by patients and is a temporary treatment, performed in conjunction with other therapies.

Stomachache

Definition

A stomachache is **pain** in the abdomen, between the bottom of the ribcage and the crease of the groin. Stomachaches are common in children and can have many causes—physical, psychological, and emotional.

Demographics

All children have occasional stomachaches. Stomachaches account for many visits to doctors and emergency rooms, as well as many missed school days. Approximately one third of children have been seen by a physician for abdominal pain by the age of 15, but only a small proportion of these represent serious problems. Complaints of abdominal pain are more common in children under age 11 than in older children and teens.

Chronic or recurrent abdominal pain (RAP) affects as many as 15% of children, especially between the ages of 4 and 12. In addition, as many as 2% of all children may experience abdominal migraines. Females are more affected by these than males.

Description

Although parents may be frightened or frustrated by their child's stomachaches—especially when the cause is not obvious—abdominal pain that lasts less than three hours is rarely serious. There are different types of stomachaches:

- A localized stomachache is pain that is limited to one part of the abdomen.
- A generalized stomachache is pain involving at least half of the abdomen. It can occur with many different illnesses and conditions and usually resolves without medical treatment.
- A cramping-type stomachache is often relieved by passing gas or stool.
- Chronic abdominal pain or RAP, also called functional abdominal pain, is defined as occurring at least once a month for at least three months and is severe enough to interfere with a child's activities. "Functional" means that the pain is real, but is not caused by a disease or other medical condition. It may be related to diet, stress, psychological or emotional problems, or nervous system immaturity or increased sensitivity.
- Abdominal migraines are stomachaches or cramping, usually near the navel or midline, that typically occur in reaction to the same triggers that cause migraine headaches.

Risk factors

Risk factors for stomachaches depend on the underlying physical, psychological, or emotional causes. Depression and **anxiety disorders** are risk factors for RAP in children and adolescents. Recurrent stomachaches in preschoolers have been shown to correlate with maternal depression. Abdominal migraines usually occur in children with a family history of migraine.

Causes and symptoms

Stomachaches in children are rarely serious and often have no identifiable cause. Mild stomachaches are often caused by overeating, gas pains, or **indigestion**. Foods that are too spicy or greasy can give children stomachaches. Changes in eating habits or bowel movements are also common causes, particularly in children under age 12. Constipation—the inability to pass a stool—is one of the most common causes of lower abdominal cramping.

Toddlers do not necessarily distinguish between physical pain and physical or emotional needs. Thus, a stomachache in a young child can indicate **fatigue**, hunger, or the need for a bowel movement.

Strep throat, caused by the *Streptococcus pyogenes* bacterium, accounts for up to 10% of acute stomachaches in children. Other infections that can cause stomachaches include:

- gastroenteritis or stomach flu—a viral infection that causes stomach cramps, diarrhea, and/or vomiting
- food poisoning—often caused by bacteria from undercooked or spoiled food—that can also cause severe diarrhea and/or vomiting lasting less than 12 hours
- a cough

- an ear infection
- chicken pox
- urinary tract infection
- pneumonia
- parasitic infections

Other physical causes of stomachaches in children include:

- swallowing air (aerophagia), which can result from anxiety or fear or from chewing gum or drinking carbonated beverages
- acid reflux or gastroesophageal reflux disease (GERD), in which stomach contents back up or reflux into the esophagus
- menstruation in girls
- lactose intolerance or difficulty digesting lactose—the sugar in milk products
- other food intolerances
- food allergies, such as a peanut allergy
- celiac disease—an inherited immune system response to gluten in flour
- latex allergy
- excessive caffeine
- irritable bowel syndrome
- inflammatory bowel disease
- poisoning from a plant, mushroom, drug, or chemical
- various medications, including drugs that have constipation as a side effect
- a swallowed foreign object
- injury to the abdomen

Pain that starts near the navel and progresses to severe pain in the lower right side of the abdomen can suggest **appendicitis**. Other symptoms of appendicitis include **fever**, loss of appetite, **vomiting**, and increasingly severe pain. Other rare but serious causes of stomachaches include:

- lead poisoning
- kidney infection
- a blocked intestine
- intussusception—slippage of a length of intestine into an adjacent portion, usually resulting in intestinal obstruction
- intestinal malrotation or twisting of a portion of the intestine

Stomachaches—especially RAP—in children aged three and older are very often stress-related. Stress- or anxiety-related causes of abdominal pain can include:

- separation anxiety, as when starting school
- social anxiety, such as attending a birthday party
- performance anxiety, such as a school exam
- over-excitement
- worry
- fear
- bullying
- abuse
- neglect
- depression
- anxiety disorders such as post-traumatic stress syndrome (PTSD)

Stomachaches can come on suddenly (acute) or persist for weeks or months (chronic). Stomachaches that last less than five minutes, even if they recur for many days, are unlikely to be serious. Stomach pain may be dull, sharp, or recurring cramps. The specific symptoms of a stomachache may suggest the cause:

- Indigestion or stomach flu can cause generalized abdominal pain.
- Pain and nausea or vomiting from a minor abdominal injury often subsides in just a few minutes.
- Stomachache, chest pain, and coughing are the most common symptoms of GERD in children.
- The closer the pain is to the navel, the more likely it is to be functional abdominal pain.
- When a stomachache is the only symptom, it is most often functional (the "Rule of Ones").
- A mild generalized pain or cramps that become more severe over a period of hours may suggest an intestinal blockage.
- Localized pain that occurs suddenly and worsens can indicate a serious problem, such as inflammation of an abdominal organ, appendicitis, gallbladder disease, or peptic ulcer disease.
- Severe sudden pain or pain that increases with coughing or movement is occasionally a symptom of a serious medical problem.
- Symptoms of abdominal migraines can include sudden severe pain across the midline that may last for an hour or up to three days, as well as nausea, vomiting, paleness, and an inability to eat.

Although an older child will complain of a stomachache and can point to the area of pain and describe its severity, children younger than five or six may not be able to describe their stomachache accurately. Young children may simply hold their belly or point to it. Babies may fuss and cry, draw their legs up toward their bellies, or refuse to eat.

A physician should be consulted if a child has severe sudden abdominal pain, new mild abdominal

WWW.BOOKBAZ.IR

KEY TERMS

Abdominal migraine—A variant form of a migraine headache; moderate to severe midline abdominal pain, usually occurring in children with a family history of migraine.

Appendicitis—Inflammation of the appendix—a narrow blind tube in the lower right abdomen.

Cognitive-behavioral therapy (CBT)—Treatment that identifies negative thoughts and behaviors and helps develop more positive approaches.

Constipation—The delayed or infrequent passage of dry, hard feces.

Functional pain—Pain that does not have a structural or organic cause.

Gastroenteritis—Stomach flu; inflammation of the lining of the stomach and intestines.

Gastroesophageal reflux disease (GERD)—Recurrent heartburn or acid indigestion caused by leakage of the stomach contents into the esophagus.

Recurrent abdominal pain (RAP)—Functional abdominal pain; stomachaches in children that recur at least once a month and that are not caused by an underlying medical condition.

pain that becomes more severe over a period of hours or days, or chronic or frequent stomachaches that interfere with normal activities such as school, play, eating, or sleeping through the night. A stomachache accompanied by any of the following symptoms also requires medical consultation:

- severe vomiting
- chronic severe diarrhea
- gastrointestinal bleeding
- unexplained fever
- persistent pain in the right side of the abdomen
- weight loss
- slow growth
- a family history of inflammatory bowel disease

A stomachache may be a medical emergency if the child:

- appears to be very ill
- becomes still or cannot stand or walk
- may have been poisoned by a plant, mushroom, medication, or chemical
- has had recent abdominal injury
- has a fever above 104°F (40°C) that is not reduced with fever medication
- is severely dehydrated
- is having difficulty breathing

Diagnosis

Examination

The healthcare provider will take a medical history and perform a **physical examination**, looking for signs of swelling and pressing on the child's belly to identify painful points. The physician will ask for information about the stomachache including:

- its intensity—mild, moderate, or severe
- whether the pain is crampy, a steady ache, sharp, or burning
- localization
- constancy
- duration
- recurrence
- foods, activities, or other factors that improve or worsen the pain
- any accompanying symptoms
- any other factors such as injury, recent travel, or drinking untreated water

Tests

Stomachaches do not usually require diagnostic tests. If appendicitis or another serious condition is suspected, then blood tests may be performed.

Procedures

Depending on the suspected cause of the stomachache, **ultrasound** imaging may be performed. X rays also may be taken.

Treatment

Treatment of stomachaches depends on the suspected cause. They often do not require treatment. A special diet or specific eating instructions may be suggested. If **stress**, **anxiety**, or other psychological or emotional causes are suspected, the child may be referred to a psychologist or other

mental health professional. Appendicitis requires an **appendectomy**, which is surgical removal of the appendix.

Drugs

Medications, especially **aspirin** and other **nonsteroidal anti-inflammatory drugs** (NSAIDs) such as ibuprofen and naproxen, can irritate the stomach lining and worsen stomachaches. If the stomachache is accompanied by a fever above 102°F (39°C), a child may be given an appropriate dose of **acetaminophen** (Tylenol). Children should not be given a laxative for stomach cramps.

Children with GERD may be treated with drugs called **proton pump inhibitors** that suppress stomach acid. In 2008 the U.S. Food and Drug Administration (FDA) approved esomeprazole (Nexium) for the short-term treatment of GERD in children aged 1 to 11.

Alternatives

Peppermint tea, peppermint oil capsules, or ginger can help relieve mild stomachaches. Behavioral interventions have had the most success in reducing or eliminating RAP. These therapies include:

- cognitive-behavioral therapy (CBT)
- guided imagery
- distraction therapy
- relaxation techniques, including breathing and progressive muscle relaxation
- biofeedback
- self-hypnosis
- coping skills for children and parents

Home remedies

Stomachaches are most often treated at home. Mild stomachaches may be treated by:

- bed rest
- consuming plenty of clear fluids (water, broth, tea, or fruit juice diluted with water) to prevent dehydration
- taking frequent, small sips of fluids
- eating several small meals instead of two or three large meals
- eating mild foods, such as rice, dry toast, crackers, gelatin, or applesauce
- avoiding high-fat and spicy foods, most fruits, and caffeinated and carbonated drinks for at least 48 hours after symptoms have passed
- having a child sit on the toilet and try to pass a stool, which can relieve stomach pain due to constipation or diarrhea
- sitting in warm water to relax the anus and help release stool
- preparing for a child to vomit by having a pan ready, since young children may refer to nausea as a tummy ache

Dietary changes have not been shown to be effective in treating frequent stomachaches in children. However, increasing dietary fiber is a simple and inexpensive way to help some children.

Prognosis

Most mild stomachaches clear up within 30 minutes to 2 hours. Stomach cramps from **gastroenteritis** often precede each bout of vomiting and **diarrhea** and may last for several days. Stomachaches from **food poisoning** usually last less than 12 hours. With stomachaches that have serious causes, such as appendicitis, the pain continues to worsen and becomes constant.

Young children with RAP are more likely than other children to have behavioral problems and they are at greater risk for developing anxiety disorders as young adults. Children with abdominal migraines usually develop migraine headaches as they become older.

Prevention

Stomachaches in children are often preventable. Parents should ensure that their children:

- get plenty of sleep
- develop regular eating habits
- wash their hands before eating
- eat slowly
- avoid overeating
- avoid eating before bed
- have regular bowel movements and develop regular bowel habits
- eat fiber-rich foods that encourage regular bowel movements
- have only limited chewing gum and carbonated beverages to prevent swallowing air
- always correctly use car child-safety seats or seat belts to prevent abdominal injuries

Although children require less dietary fiber than adults, fiber may help prevent stomachaches in some children. The American Dietetic Association's formula for daily fiber intake, in grams, for children

WWW.BOOKBAZ.IR

aged 3 to 18, is the child's age plus five grams. Fruits, vegetables, and whole grains are good sources of fiber. Dietary fiber should be increased gradually. Children should drink extra water or milk when increasing dietary fiber.

Stomatitis

Definition

Inflammation of the mucous lining of any of the structures in the mouth, which may involve the cheeks, gums, tongue, lips, and roof or floor of the mouth. The word *stomatitis* literally means inflammation of the mouth. The inflammation can be caused by conditions in the mouth itself, such as poor **oral hygiene**, poorly fitted dentures, or from mouth **burns** from hot food or drinks, or by conditions that affect the entire body, such as medications, allergic reactions, or infections.

Description

Stomatitis is an inflammation of the lining of any of the soft-tissue structures of the mouth. Stomatitis is usually a painful condition, associated with redness, swelling, and occasional bleeding from the affected area. **Bad breath** (halitosis) may also accompany the condition. Stomatitis affects all age groups, from the infant to the elderly.

Causes and symptoms

A number of factors can cause stomatitis; it is a fairly common problem in the general adult population in North America. Poorly fitted oral appliances, cheek biting, or jagged teeth can persistently irritate the oral structures. Chronic mouth breathing due to plugged nasal airways can cause dryness of the mouth tissues, which in turn leads to irritation. Drinking beverages that are too hot can burn the mouth, leading to irritation and **pain**. Diseases, such as herpetic infections (the **common cold** sore), **gonorrhea**, **measles**,

This patient is afflicted with stomatitis, a common inflammatory disease of the mouth. *(Custom Medical Stock Photo, Inc.)*

leukemia, **AIDS**, and lack of vitamin C can present with oral signs. Other systemic diseases associated with stomatitis include inflammatory bowel disease (IBD) and Behçet's syndrome, an inflammatory multisystem disorder of unknown cause.

Aphthous stomatitis, also known as recurrent aphthous **ulcers** (RAU) or **canker sores**, is a specific type of stomatitis that presents with shallow, painful ulcers that are usually located on the lips, cheeks, gums, or roof or floor of the mouth. These ulcers can range from pinpoint size to up to 1 in (2.5 cm) or more in diameter. Though the causes of canker sores are unknown, nutritional deficiencies, especially of vitamin B_{12}, folate, or iron is suspected. Generalized or contact stomatitis can result from excessive use of alcohol, spices, hot food, or tobacco products. Sensitivity to mouthwashes, toothpastes, and lipstick can irritate the lining of the mouth. Exposure to heavy metals, such as mercury, lead, or bismuth can cause stomatitis. Thrush, a fungal infection, is a type of stomatitis.

Diagnosis

Diagnosis of stomatitis can be difficult. A patient's history may disclose a dietary deficiency, a systemic disease, or contact with materials causing an allergic reaction. A **physical examination** is done to evaluate the oral lesions and other skin problems. Blood tests may be done to determine if any infection is present. Scrapings of the lining of the mouth may be sent to the laboratory for microscopic evaluation, or cultures of the mouth may be done to determine if an infectious agent may be the cause of the problem.

Treatment

The treatment of stomatitis is based on the problem causing it. Local cleansing and good oral hygiene are fundamental. Sharp-edged foods such as peanuts, tacos, and potato chips should be avoided. A soft-bristled toothbrush should be used, and the teeth and gums should be brushed carefully; the patient should avoid banging the toothbrush into the gums. Local factors, such as ill-fitting dental appliances or sharp teeth, can be corrected by a dentist. An infectious cause can usually be treated with medication. Systemic problems, such as AIDS, leukemia, and anemia are treated by the appropriate medical specialist. Minor mouth burns from hot beverages or hot foods will usually resolve on their own in a week or so. Chronic problems with aphthous stomatitis are treated by first correcting any vitamin B_{12}, iron, or folate deficiencies. If those therapies are unsuccessful, medication can be prescribed which can be applied to each aphthous ulcer with a cotton-tipped applicator. This therapy is successful with a limited number of patients. More recently, low-power treatment with a carbon dioxide laser has been found to relieve the discomfort of recurrent aphthae. Major outbreaks of aphthous stomatitis can be treated with tetracycline **antibiotics** or **corticosteroids**. Valacyclovir has been shown to be effective in treating stomatitis caused by herpesviruses.

Patients may also be given topical anesthetics (usually a 2% lidocaine gel) to relieve pain and a protective paste (Orabase) or a coating agent like Kaopectate to protect eroded areas from further irritation from dentures, braces, or teeth.

KEY TERMS

Aphthous stomatitis—A specific type of stomatitis presenting with shallow, painful ulcers. Also known as *canker sores*.

Stomatitis—Inflammation of the lining of the mouth, gums, or tongue.

Thrush—A form of stomatitis caused by *Candida* fungi and characterized by cream-colored or bluish patches on the tongue, mouth, or pharynx.

Alternatives

Alternate treatment of stomatitis mainly involves prevention of the problem. Patients with such dental appliances as dentures should visit their dentist on a regular basis. Patients with systemic diseases or chronic medical problems need to ask their healthcare provider what types of oral problems they can expect from their particular disease. These patients must also contact their medical clinic at the first sign of problems. Common sense needs to be exercised when consuming hot foods or drinks. Use of tobacco products should be discouraged. Alcohol should be used in moderation. Mouthwashes and toothpastes known to the patient to cause problems should be avoided.

Botanical medicine can assist in resolving stomatitis. One herb, calendula (*Calendula officinalis*), in tincture form (an alcohol-based herbal extract) and diluted for a mouth rinse, can be quite effective in treating aphthous stomatitis and other manifestations of stomatitis.

Subsequently, a group of researchers in Brazil reported that an extract made from the leaves of

WWW.BOOKBAZ.IR

Trichilia glabra, a plant found in South America, is effective in killing several viruses that cause stomatitis.

Prognosis

The prognosis for the resolution of stomatitis is based on the cause of the problem. Many local factors can be modified, treated, or avoided. Infectious causes of stomatitis can usually be managed with medication, or, if the problem is being caused by a certain drug, by changing the offending agent.

Prevention

Stomatitis caused by local irritants can be prevented by good oral hygiene, regular dental checkups, and good dietary habits. Problems with stomatitis caused by systemic disease can be minimized by good oral hygiene and closely following the medical therapy prescribed by the patient's healthcare provider.

Stool culture

Definition

A stool culture is a test to identify bacteria in patients with a suspected infection of the digestive tract. A sample of the patient's feces is placed in a special medium. Any bacteria that grows in the culture are identified using a microscope and biochemical tests. The test may also be referred to as a fecal culture.

Purpose

Stool culture is performed to identify bacteria or other organisms in persons with symptoms of gastrointestinal infection, most commonly **diarrhea**. Identification of the organism is necessary to determine the proper course of treatment or to trace the cause of an outbreak or epidemic of certain types of diarrhea.

According to the Centers for Disease Control and Prevention (CDC), doctors are most likely to order a stool culture for patients with any of the following characteristics:

- AIDS
- bloody stools
- diarrhea lasting longer than three days
- high fever
- history of recent travel abroad
- severe dehydration

Description

To obtain a specimen for culture, the patient is asked to collect a stool sample into a special sterile container. In some cases, the container may contain a transport solution. Specimens may need to be collected on three consecutive days. It is important to return the specimen to the doctor's office or the laboratory in the time specified by the physician or nurse. Laboratories do not accept stool specimens contaminated with water, urine, or other materials, including toilet paper.

The culture test involves placing a sample of the stool on a special substance, called a medium, that provides nutrients for certain organisms to grow and reproduce. The medium is usually a thick gel-like substance. The culture is done in a test tube or on a flat round culture plate and is incubated at the proper temperature for growth of the bacteria. After a colony of bacteria grows in the medium, the type of bacteria is identified by observing the colony's growth, physical characteristics, and microscopic features. The bacteria

may be dyed with special stains that make it easier to identify features specific to particular bacteria.

Although most intestinal infections are caused by bacteria, in some cases a fungal or viral culture may be necessary. The most common bacterial infections of the digestive tract are caused by *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia*. Patients taking certain **antibiotics** may be susceptible to infection with *Clostridium difficile*. In some cases, as with *Clostridium difficile*, the stool culture is used to detect the toxin (poison or harmful chemical) produced by the bacteria.

Patients with **AIDS** or other immune system diseases may develop gastrointestinal infections caused by fungi, such as *Candida*, or viral organisms, including cytomegalovirus.

Several intestinal parasites may cause gastrointestinal infection and diarrhea. Parasites are not cultured but are identified microscopically in a stool ova and parasites test, also referred to as a stool O & P test.

KEY TERMS

Bismuth—A substance used in medicines to treat diarrhea, nausea, and indigestion.

Enteric—Pertaining to the intestine.

Enterotoxigenic—Refers to an organism that produces toxins in the gastrointestinal tract that cause such things as vomiting, diarrhea, and other symptoms of food poisoning.

Feces—Material excreted by the intestines.

Flora—Refers to normal bacteria found in a healthy person.

Gastrointestinal—Referring to the digestive tract; the stomach and intestines.

Psyllium hydrophilic mucilloid—A plant material contained in some laxatives.

Sterile—Free of microorganisms.

Toxin—A poison; usually refers to protein poisons produced by bacteria, animals, and some plants.

Preparation

The physician or other healthcare provider will ask the patient for a complete medical history and perform a **physical examination** to determine possible causes of the gastrointestinal problem. Information about the patient's diet, any medications taken, and recent travel may provide clues to the identity of possible infectious organisms.

Stool culture normally does not require any special preparation. Patients do not need to change their diet before collecting the specimen. Intake of some substances can contaminate the stool specimen and should not be taken the day before collection. These substances include castor oil, bismuth, certain antibiotics, and laxative preparations containing psyllium hydrophilic mucilloid.

Patients may wish to find out ahead of time if their insurance covers stool cultures. This common test is usually covered when ordered by a physician approved by the patient's insurance plan and done at an approved laboratory.

Aftercare

An antibiotic sensitivity test may be done after a specific bacterium is identified. This test shows which antibiotics will be most effective for treating the infection.

Results

The length of time needed to perform a stool culture depends on the laboratory where it is done and the culture methods used. Stool culture usually takes 72 hours or longer to complete. Some organisms may take several weeks to grow in a culture.

Bacteria that are normally found in the intestines include *Pseudomonas* and *Escherichia coli*. These enteric bacteria (bacteria of the gastrointestinal system) are considered normal flora and usually do not cause infection in the digestive tract.

Abnormal results

Bacteria that do not normally inhabit the digestive tract and that are known to cause gastrointestinal infection include *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia*. *Clostridium difficile* produces a toxin that can cause severe diarrhea. Other bacteria that produce toxins are *Staphylococcus aureus*, *Bacillus cereus*, and enterotoxigenic (producing disease in the digestive system) *Escherichia coli*. Although *Escherichia coli* is a normal bacteria found in the intestines, the enterotoxigenic type of this bacteria can be acquired from consuming contaminated meat, produce, or juice. It produces a toxin that causes severe inflammation and bleeding of the colon.

Alternatives

Newer methods of testing stool samples for specific disease organisms include various forms of polymerase chain reaction (PCR) assays. One type that has been used to test for several different types of intestinal viruses at the same time is the RT-PCR, which stands for reverse transcriptase polymerase chain reaction. This assay measures changes in an organism's messenger ribonucleic acid (RNA). RT-PCR assays have several advantages over standard stool cultures: they require only very small samples of material, they can be performed much more rapidly, and they can be used to test environmental water for virus contamination as well as human stool samples.

Stool fat test

Definition

Stool fats, also known as fecal fats or lipids, are fats that are excreted in feces. When secretions from the pancreas and liver are adequate, emulsified dietary fats are almost completely absorbed in the small intestine. When a malabsorption disorder or other condition disrupts this process, excretion of fat in the stool increases.

Purpose

This test evaluates the digestion of fats by determining excessive excretion of lipids in patients exhibiting signs of malabsorption, such as weight loss, abdominal distention, and scaly skin.

Description

Excessive excretion of fecal fat is called steatorrhea, a condition that is suspected when the patient has large, "greasy," and foul-smelling stools. Both digestive and absorptive disorders can cause steatorrhea. Digestive disorders affect the production and release of the enzyme lipase from the pancreas or bile from the liver, which are substances that aid in the digestion of fats. Absorptive disorders disturb the absorptive and enzyme functions of the intestine. Any condition that causes malabsorption or maldigestion is associated with increased fecal fat. As an example, children with **cystic fibrosis** have mucous plugs that block the pancreatic ducts. The absence or significant decrease of the pancreatic enzymes amylase, lipase, trypsin, and chymotrypsin limits fat protein and carbohydrate digestion, resulting in steatorrhea due to fat malabsorption.

Both qualitative and quantitative tests are used to identify excessive fecal fat. The qualitative test involves staining a specimen of stool with a special dye, then examining it microscopically for evidence of malabsorption, such as undigested muscle fiber and various fats. The quantitative test involves drying and weighing a three-day stool specimen, then using an extraction technique to separate the fats, which are subsequently evaporated and weighed. This measurement of the total output of fecal fat per day is the most reliable test for steatorrhea.

Precautions

Drugs that may increase fecal fat levels include **enemas** and **laxatives**, especially mineral oil. Drugs that may decrease fecal fat include Metamucil and barium. Other substances that can affect test results include alcohol, potassium chloride, **calcium** carbonate, neomycin, kanamycin, and other broad-spectrum **antibiotics**.

Preparation

This test requires a 72-hour stool collection. The patient should abstain from alcohol during this time and maintain a high-fat diet (100 grams [g] per day) for three days before the test and during the collection

KEY TERMS

Enzyme—A protein that changes the rate of a chemical reaction within the body without being depleted in the reaction.

Lipid—Any organic compound that is greasy and insoluble in water but soluble in alcohol. Fats, waxes, and oils are examples of lipids.

Malabsorption—Poor absorption of nutrients.

period. The patient should call the laboratory for instructions on how to collect the specimen.

Results

Reference values vary from laboratory to laboratory but are generally found within the range of 5–7 grams per 24-hour period.

It should be noted that children, especially infants, cannot ingest the 100 g/day of fat that is suggested for the test. Therefore, an alternate method determines the difference between ingested fat and fecal fat, expressed as a percentage. The figure, called the fat retention coefficient, is 95% or greater in healthy children and adults. A low value is indicative of steatorrhea.

Abnormal results

Increased fecal fat levels are found in cystic fibrosis; malabsorption secondary to other conditions like Whipple's disease or Crohn's disease; maldigestion secondary to pancreatic or bile duct obstruction; and "short-gut" syndrome secondary to surgical resection, bypass, or congenital anomaly.

Stool O & P test

Definition

The stool O & P test is the stool ova and parasites test. In this test, a stool sample is examined for the presence of intestinal parasites and their eggs, which are called ova.

Purpose

The ova and parasites test is performed to look for and identify intestinal parasites and their eggs in persons with symptoms of gastrointestinal infection. Patients may have no symptoms, or experience **diarrhea**, blood in the stools, and other gastrointestinal distress. Identification of a particular parasite indicates the cause of the patient's disease and determines the medication needed to treat it.

Precautions

Stool O & P is performed if an infection of the digestive tract is suspected. The test has no harmful effects.

Description

Examination of the stool for ova and parasites is done to diagnose parasitic infection of the intestines. The test may be done in the doctor's office or a laboratory. The patient collects a stool sample in one or more sterile containers containing special chemical fixatives. The feces should be collected directly into the container. It must not be contaminated with urine, water, or other materials. Three specimens are often needed—collected every other day, or every third day. However, as many as six specimens may be needed to diagnose the amoeba *Entamoeba histolytica*. The specimen does not need to be refrigerated. It should be delivered to the doctor's office or laboratory within 12 hours.

In the laboratory, the stool sample is observed for signs of parasites and their eggs. Some parasites are large enough to be seen without a microscope. For others, microscope slides are prepared with fresh unstained stool, and with stool dyed with special stains. These preparations are observed with a microscope for the presence of parasites or their eggs.

An unstained stool examination for ova and parasites normally only takes a few minutes. If specimen staining and other preparation is done, the test may take longer. When the specimen is sent to a laboratory, the results may take 8 to 24 hours to be reported.

WWW.BOOKBAZ.IR

The most common intestinal parasites in North America that cause infections are:

- roundworms: *Ascaris lumbricoides*
- hookworms: *Necator americanus*
- pinworms: *Enterobius follicularis*
- tapeworms: *Diphyllobothrium latum*, *Taenia saginata*, and *Taenia solium*
- protozoa: *Entamoeba histolytica* (an amoeba), and *Giardia lamblia* (a flagellate)

Numerous other parasites are found in other parts of the world. These may be contracted by travelers to other countries. Patients with acquired immune deficiency syndrome (**AIDS**) or other immune system disorders are commonly infected with the parasites in the *Microsporidia* family, *Cryptosporidium*, and *Isospora belli*.

Insurance coverage for stool ova and parasites may vary among different insurance plans. This test usually is covered if ordered by a physician approved by the patient's insurance plan, and if it is done at an approved laboratory.

KEY TERMS

Amoeba—A type of protozoa (one-celled animal) that can move or change its shape by extending projections of its cytoplasm.

Bismuth—A substance used in medicines to treat diarrhea, nausea, and indigestion.

Cryptosporidium—A type of parasitic protozoa.

Feces—Material excreted by the intestines.

Flagellate—A microorganism that uses flagella (hair-like projections) to move.

Gastrointestinal—Referring to the digestive tract; the stomach and intestines.

Isospora belli—A type of parasitic protozoa.

Microsporida—A type of parasitic protozoa.

Ova—Eggs.

Parasite—An organism that lives on or inside another living organism (host), causing damage to the host.

Pathogenic—Disease-causing.

Protozoa—One-celled eukaryotic organisms belonging to the kingdom Protista.

Sterile—Free of microorganisms.

Preparation

The physician, or other healthcare provider, will ask the patient for a complete medical history, and perform a **physical examination** to determine possible causes of the gastrointestinal symptoms. Information about the patient's diet, any medications taken, and recent travel may provide clues to the identity of possible infectious parasites.

Collecting a stool sample for ova and parasite detection normally does not require any special preparation. Patients do not need to change their diet before collecting the specimen. Patients should avoid taking any medications or treatments containing mineral oil, castor oil, or bismuth; magnesium or other antidiarrheal medicines; or **antibiotics** for seven to ten days before collecting the specimen. Sometimes samples taken over multiple days may be required.

Results

Normally, parasites and eggs should not be found in stools. Some parasites are not pathogenic, which means they do not cause disease. If these are found, no treatment is necessary.

Abnormal results

The presence of any pathogenic parasite indicates an intestinal parasitic infection. Depending on the parasite identified, other tests may need to be performed to determine if the parasite has invaded other parts of the body. Some parasites travel from the intestines to other parts of the body and may already have caused damage to other tissues by the time a diagnosis is made. For example, the roundworm, *A. lumbricoides*, penetrates the intestinal wall and can cause inflammation in the abdomen. It can also migrate to the lungs and cause **pneumonia**. This kind of injury can occur weeks before the roundworm eggs show up in the stool.

Other types of damage caused by intestinal parasites include anemia due to hemorrhage caused by hookworms, and anemia caused by depletion of vitamin B_{12} through the action of tapeworms.

When a parasite is identified, the patient can be treated with the appropriate medications to eliminate the parasite.

Alternatives

Pinworms may be detected by using a tape test. After waking, the person suspected of having pinworms should place a 1 in. piece of clear cellophane tape over the anus. If eggs are present, they will stick to the tape. The tape should then be placed (sticky-side down) on a glass slide and given to a physician for analysis.

Strabismus

Definition

Strabismus is a condition in which the eyes do not point in the same direction. It can also be referred to as a tropia or squint.

Description

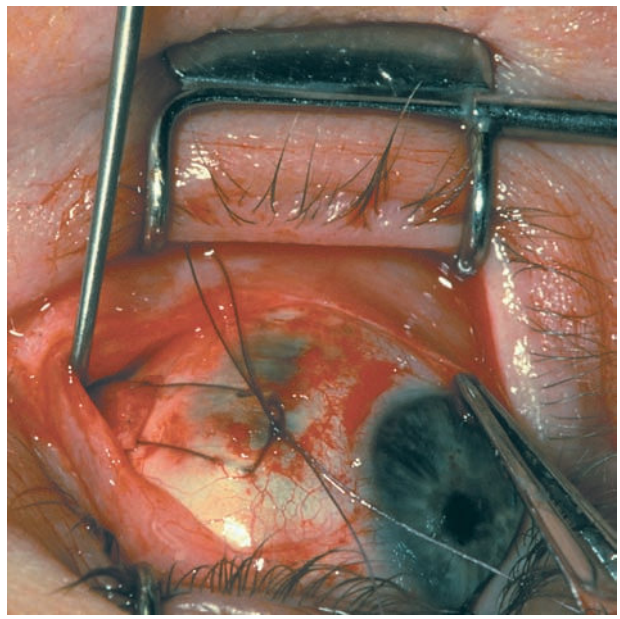
Strabismus occurs in 2–5% of all children. About half are born with the condition, which causes one or both eyes to turn:

- inward (esotropia or "crossed eyes")
- outward (exotropia or "wall eyes")
- upward (hypertropia)
- downward (hypotropia)

Strabismus is equally common in boys and girls. It sometimes runs in families.

Types of strabismus

Esotropia is the most common type of strabismus in infants. Accommodative esotropia develops in children under age two who cross their eyes when focusing on objects nearby. This usually occurs in children who are moderately to highly farsighted (hyperopic).



A close-up of ophthalmic surgery being performed to correct strabismus. *(Custom Medical Stock Photo, Inc.)*

Another common form of strabismus, exotropia, may only be noticeable when a child looks at far-away objects, daydreams, or is tired or sick.

Sometimes the eye turn is always in the same eye; however sometimes the turn alternates from one eye to the other'.

Most children with strabismus have comitant strabismus. No matter where they look, the degree of deviation does not change. In incomitant strabismus, the amount of misalignment depends upon which direction the eyes are pointed.

False strabismus (pseudostrabismus)

A child may appear to have a turned eye; however, this appearance may actually be due to one of the following:

- extra skin that covers the inner corner of the eye
- a broad, flat nose
- eyes set unusually close together or far apart

This condition, false strabismus, usually disappears as the child's face grows. An eye doctor needs to determine whether the eyeturn is true or pseudostrabismus.

With normal vision, both eyes send the brain the same message. This binocular fixation (both eyes looking directly at the same object) is necessary to see three-dimensionally and to aid in depth perception. When an eye is misaligned, the brain receives two different

WWW.BOOKBAZ.IR

images. Young children learn to ignore distorted messages from a misaligned eye, but adults with strabismus often develop double vision (diplopia).

A baby's eyes should be straight and parallel by three or four months of age. A child who develops strabismus after the age of eight or nine years is said to have adult-onset strabismus.

Causes and symptoms

Strabismus can be caused by a defect in muscles or the part of the brain that controls eye movement. It is especially common in children who have:

- brain tumors
- cerebral palsy
- Down syndrome
- hydrocephalus
- other disorders that affect the brain

Diseases that cause partial or total blindness can cause strabismus. So can extreme farsightedness, **cataracts**, eye injury, or having much better vision in one eye than the other.

In adults, strabismus is usually caused by:

- diabetes
- head trauma
- stroke
- brain tumor
- other diseases affecting nerves that control eye muscles

The most obvious symptom of strabismus is an eye that isn't always straight. The deviation can vary from day to day or during the day. People who have strabismus often squint in bright sunlight or tilt their heads to focus their eyes.

Diagnosis

Every baby's eyes should be examined by the age of six months. A baby whose eyes have not straightened by the age of four months should be examined to rule out serious disease.

A pediatrician, family doctor, ophthalmologist, or optometrist licensed to use diagnostic drugs uses drops that dilate the pupils and temporarily paralyze eye-focusing muscles to evaluate visual status and ocular health. Early diagnosis is important. Some eye turns may be a result of a tumor. Untreated strabismus can damage vision in the unused eye and possibly result in lazy eye (**amblyopia**).

Treatment

Preserving or restoring vision and improving appearance may involve one or more of the following:

- glasses to aid in focusing and straighten the eye(s)
- patching to force infants and young children to use and straighten the weaker eye
- eye drops or ointments as a substitute for patching or glasses, or to make glasses more effective
- surgery to tighten, relax, or reposition eye muscles
- medication injected into an overactive eye muscle to allow the opposite muscle to straighten the eye
- vision training (also called eye exercises)

Prognosis

Early consistent treatment usually improves vision and appearance. The most satisfactory results are achieved if the condition is corrected before the age of seven years old.

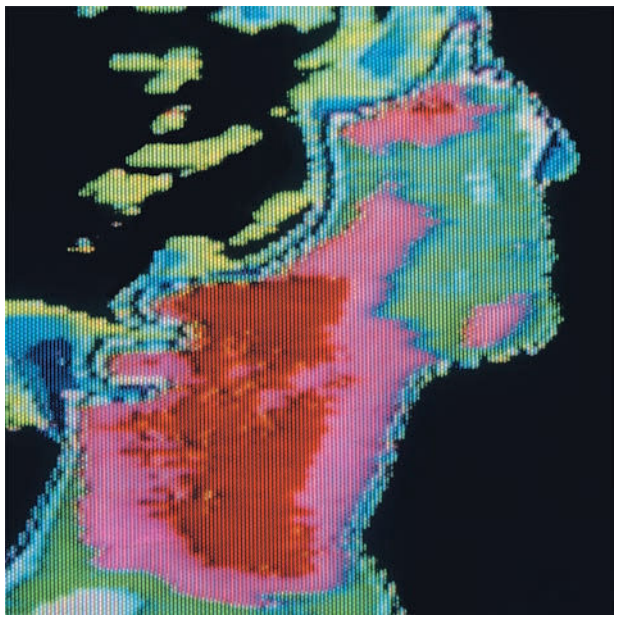
Strep throat

Definition

Streptococcal **sore throat**, or strep throat as it is more commonly called, is an infection of the mucous membranes lining the pharynx (throat). Sometimes the tonsils are also infected (**tonsillitis**). The disease is caused by group A *Streptococcus* bacteria. Untreated strep throat may develop into **rheumatic fever** or other serious conditions.



A thermographic image showing a streptococcal sore throat, or strep throat. *(© Howard Sochurek/Corbis.)*

Description

Strep throat accounts for between 5–10% of all sore throats. Although anyone can get strep throat, it is most common in school-age children. People who smoke, who are fatigued, run down, or who live in damp, crowded conditions are also more likely to become infected. Children under age two and adults who are not around children are less likely to get the disease; their sore throats are usually caused by viruses, not strep bacteria.

Strep throat occurs most frequently from November to April. The disease passes directly from person to person by coughing, sneezing, and close contact. Very occasionally the disease is passed through food, when a food handler infected with strep bacteria accidentally contaminates food by coughing or sneezing. Statistically, if someone in the household is infected, one out of every four other household members is likely to get strep throat within two to seven days.

Causes and symptoms

A person with strep throat suddenly develops a painful sore throat one to five days after being exposed to streptococcus bacteria. The **pain** is indistinguishable from sore throats caused by other types of bacteria or viruses.

The infected person usually feels tired and has a **fever**, sometimes accompanied by chills, **headache**, muscle aches, swollen lymph glands, and nausea. Young children may complain of abdominal pain. The tonsils look swollen and are bright red, with white or yellow patches of pus on them. Sometimes the roof of the mouth is red or has small red spots. Often a person with strep throat has **bad breath**.

Despite these common symptoms, strep throat can be deceptive. It is possible to have the disease and not show any of these symptoms. Many young children complain only of a headache and stomach ache, without the characteristic sore throat symptoms.

Occasionally, within a few days of developing the sore throat, an individual may develop a fine, rough, sunburn-like rash over the face and upper body and have a fever of 101–104°F (38.3–40°C). The tongue becomes bright red, with a flecked, strawberry-like appearance. When a rash develops, this form of strep throat is called **scarlet fever**. The rash is a reaction to toxins (poisons) released by streptococcus bacteria. Scarlet fever is no more dangerous than strep throat, and it is treated the same way. The rash disappears in about five days. One to three weeks later, patches of skin may peel off, as might occur with a **sunburn**, especially on the fingers and toes.

Untreated strep throat can cause rheumatic fever and rheumatic **heart disease** (damage to the heart caused by rheumatic fever). This is a serious illness, although it is uncommon in the United States. The most recent outbreak in the U. S. occurred in the mid-1980s. Worldwide, however, 90,000 people are estimated to die from rheumatic heart disease each year, with the highest rates occurring in developing countries. Rheumatic fever occurs most often in children between the ages of 5 and 15, and may have a genetic component since it seems to run in families. Although the strep throat that causes rheumatic fever is contagious, rheumatic fever itself is not.

Rheumatic fever begins one to six weeks after an untreated streptococcal infection. The joints, especially the wrists, elbows, knees, and ankles become red, sore, and swollen. The infected person develops a high fever, and possibly a rapid heartbeat when lying down, paleness, **shortness of breath**, and fluid retention. A red rash over the trunk may come and go for weeks or months. An acute attack of rheumatic fever lasts about three months.

Rheumatic fever can cause permanent damage to the heart and heart valves. It can be prevented by promptly treating **streptococcal infections** with **antibiotics**. It does not occur if all the streptococcus bacteria are killed within the first 10–12 days after infection.

WWW.BOOKBAZ.IR

In the 1990s, outbreaks of a virulent strain of group A *Streptococcus* were reported to cause a toxic-shock-like illness and a severe invasive infection called necrotizing fasciitis, which destroys skin and muscle tissue. Although these diseases are caused by group A *Streptococci*, they rarely begin with strep throat. Usually the streptococcus bacteria enter the body through a skin wound. These complications are rare. However, since the death rate in necrotizing fasciitis is 30–50%, it is wise to seek prompt treatment for any streptococcal infection.

Diagnosis

Diagnosis of a strep throat by a doctor begins with a **physical examination** of the throat and chest. The doctor will also look for signs of other illness, such as a sinus infection or **bronchitis**, and seek information about whether the patient has been around other people with strep throat. If it appears that the patient may have strep throat, the doctor will do laboratory tests.

There are two types of tests to determine if a person has strep throat. A rapid strep test can determine only the presence of streptococcal bacteria in material collected on a sterile swabb from the throat. It will not tell the doctor whether the sore throat is caused by another kind of bacteria or if it is caused by a virus. The results of a rapid strep test are available in about 20 minutes. The advantage of this test is the speed with which a diagnosis can be made.

The rapid strep test has a false negative rate of about 25%. In other words, in about one out of every four cases where no strep is detected by the rapid strep test, the patient actually does have strep throat. Because of this, when a rapid strep test is negative, the doctor often does a **throat culture**.

For a rapid strep test or a throat culture, a nurse will use a sterile swab to reach down into the throat and obtain a sample of material from the sore area. The procedure takes only a few seconds, but may cause gagging.

For a throat culture, a sample of swabbed material is cultured, or grown, in the laboratory on a medium that allows technicians to determine what kind of bacteria are present. Results take 24–48 hours. The test is very accurate and will show the presence of other kinds of bacteria besides *Streptococci*. It is important not to take any leftover antibiotics before visiting the doctor and having a throat culture. Even small amounts of antibiotics can suppress the bacteria and mask its presence in the throat culture, thus preventing the patient from getting proper treatment.

In the event that rheumatic fever is suspected, the doctor does a blood test. This test, called an antistreptolysin-O test, will tell the doctor whether the person has recently been infected with strep bacteria. This helps the doctor distinguish between rheumatic fever and **rheumatoid arthritis**.

Treatment

Strep throat is treated with antibiotics. Penicillin is the preferred medication. Oral penicillin must be taken for 10 days. Patients need to take the entire amount of antibiotic prescribed and not discontinue taking the medication when they feel better. Stopping the antibiotic early can lead to a return of the strep infection. Occasionally, a single injection of long-acting penicillin (Bicillin) is given instead of 10 days of oral treatment.

About 10% of the time, penicillin is not effective against the strep bacteria. When this happens a doctor may prescribe other antibiotics such as cefuroxime (Ceftin), cefixime (Suprax), cefpodoxime proxetil (Vantin), loracarbef (Lorabid), cefditoren (Spectracef), azithromycin (Zithromax), clindamycin (Cleocin), or a cephalosporin (Keflex, Durocef, Ceclor). Erythromycin (Eryzole, Pediazole, Ilosone), another inexpensive antibiotic, can be given to people who are allergic to penicillin. Scarlet fever is treated with the same antibiotics as strep throat.

Without treatment, the symptoms of strep throat begin subsiding in four or five days. However, because of the possibility of developing rheumatic fever, it is important to treat strep throat promptly with antibiotics. If rheumatic fever does occur, it is also treated with antibiotics. Anti-inflammatory drugs, such as **steroids**, are used to treat joint swelling. **Diuretics** are used to reduce water retention. Once the rheumatic fever becomes inactive, children may continue on low doses of antibiotics to prevent a reoccurrence. Necrotizing fasciitis is treated with hospitalization and intravenous antibiotics.

Home care for strep throat

There are **home care** steps that people can take to ease the discomfort of their strep symptoms.

- Take acetaminophen or ibuprofen for pain. Aspirin should not be given to children because of its association with an increase in Reye's Syndrome, a serious disease.

- Gargle with warm double strength tea or warm salt water, made by adding one teaspoon of salt to eight ounces of water, to relieve sore throat pain.
- Drink plenty of fluids, but avoid acidic juices like orange juice because they irritate the throat.
- Eat soft, nutritious foods like noodle soup. Avoid spicy foods.
- Avoid smoke and smoking.
- Rest until the fever is gone, then resume strenuous activities gradually.
- Use a room humidifier, as it may make sore throat sufferers more comfortable.
- Be aware that antiseptic lozenges and sprays may aggravate the sore throat rather than improve it.

Alternatives

Alternative treatment focuses on easing the symptoms of strep throat through herbs and botanical medicines. Some practitioners suggest using these treatments in addition to antibiotics, since they primarily address the comfort of the patient and not the underlying infection. Many practitioners recommend *Lactobacillus acidophilus* to offset the suppressive effects of antibiotics on the beneficial bacteria of the intestines.

Some suggested treatments include:

- Inhaling fragrances of the essential oils of lavender (*Lavandula officinalis*), thyme (*Thymus vulgaris*), eucalyptus (*Eucalyptus globulus*), sage (*Salvia officinalis*), and sandalwood (Aromatherapy).
- Gargling with a mixture of water, salt, and tumeric (*Curcuma longa*) powder or astringents, such as alum, sumac, sage, and bayberry (Ayurvedic medicine).
- Taking osha root (*Ligusticum porteri*) internally for infection or drinking tea made of sage, echinacea (*Echinacea* spp.) and cleavers (*Gallium aparine*) Osha root has an unpleasant taste many children will not accept (Botanical medicine).

Prognosis

Patients with strep throat begin feeling better about 24 hours after starting antibiotics. Symptoms rarely last longer than five days. People remain contagious until after they have been taking antibiotics for 24 hours. Children should not return to school or childcare until they are no longer contagious. Food handlers should not work for the first 24 hours after antibiotic treatment because strep infections are occasionally passed through contaminated food. People who are not treated with antibiotics can continue to spread strep bacteria for several months.

KEY TERMS

***Lactobacillus acidophilus*—**A bacteria found in yogurt that changes the balance of the bacteria in the intestine in a beneficial way.

About 10% of strep throat cases do not respond to penicillin. People who have even a mild sore throat after a 10 day treatment with antibiotic should return to their doctor. An explanation for this may be that the person is a carrier of strep but that something other than a strep bacterium is causing the sore throat.

Taking antibiotics within the first week of a strep infection will prevent rheumatic fever and other complications. If rheumatic fever does occur, the outcomes vary considerably. Some cases may be cured. In others there may be permanent damage to the heart and heart valves. In rare cases, rheumatic fever can be fatal.

Necrotizing fasciitis has a death rate of 30–50%. Patients who survive often suffer a great deal of tissue and muscle loss. Fortunately, this complication of a streptococcus infection is very rare.

Prevention

There is no way to prevent getting a strep throat. However, the risk of getting one or passing one on to another person can be minimized by:

- washing hands well and frequently, especially after nose blowing or sneezing and before food handling
- disposing of used tissues properly
- avoiding close contact with someone who has a strep throat
- not sharing food and eating utensils with anyone
- not smoking

Streptococcal antibody tests

Definition

Streptococcal infections are caused by a microorganism called *Streptococcus*. Three streptococcal antibody tests are available: the antistreptolysin O titer (ASO), the antideoxyribonuclease-B titer (anti-Dnase-B, or ADB), and the streptozyme test.

Purpose

The antistreptolysin O titer, or ASO, is ordered primarily to determine whether a previous group A *Streptococcus* infection has caused a poststreptococcal disease, such as **scarlet fever**, **rheumatic fever**, or a **kidney disease** called **glomerulonephritis**.

The anti-DNase-B (ADB) test is performed to determine a previous infection of a specific type of *Streptococcus*, group A beta-hemolytic *Streptococcus*. Identification of infections of this type are particularly important in suspected cases of acute rheumatic **fever** (ARF) or acute glomerulonephritis.

Streptozyme is a screening test used to detect antibodies to several streptococcal antigens. An antigen is a substance that can trigger an immune response, resulting in production of an antibody as part of the body's defense against infection and disease.

Precautions

For the ASO test, increased levels of fats, called beta lipoproteins, in the blood can neutralize streptolysin O and cause a false-positive ASO titer. **Antibiotics**, which reduce the number of streptococci and thereby suppress ASO production, may decrease ASO levels. **Steroids**, which suppress the immune system, consequently may also suppress ASO production. Also Group A streptococcal infections of the skin may not produce an ASO response. Antibiotics also may decrease anti-DNase-B (ADB) levels.

Description

Streptococcal infections are caused by bacteria known as *Streptococcus*. There are several disease-causing strains of streptococci (groups A, B, C, D, and G), which are identified by their behavior, chemistry, and appearance. Each group causes specific types of infections and symptoms. These antibody tests are useful for group A streptococci. Group A streptococci are the most virulent species for humans and are the cause of **strep throat**, **tonsillitis**, wound and skin infections, blood infections (septicemia), scarlet fever, **pneumonia**, rheumatic fever, Sydenham's chorea (formerly called St. Vitus' dance), and glomerulonephritis.

Although symptoms may suggest a streptococcal infection, the diagnosis must be confirmed by tests. The best procedure, and one that is used for an acute infection, is to take a sample from the infected area for culture, a means of growing bacteria artificially in the laboratory. However, cultures are useless about two to three weeks after initial infection, so the ASO, anti-DNase-B, and streptozyme tests are used to determine if a streptococcal infection is present.

Antistreptolysin O titer (ASO)

The ASO titer is used to demonstrate the body's reaction to an infection caused by group A beta-hemolytic streptococci. Group A streptococci produce the enzyme streptolysin O, which can destroy (lyse) red blood cells. Because streptolysin O is antigenic (contains a protein foreign to the body), the body reacts by producing antistreptolysin O (ASO), which is a neutralizing antibody. ASO appears in the blood serum one week to one month after the onset of a strep infection. A high titer (high levels of ASO) is not specific for any type of poststreptococcal disease, but it does indicate if a streptococcal infection is or has been present.

Serial (several given in a row) ASO testing is often performed to determine the difference between an acute or convalescent blood sample. The diagnosis of a previous strep infection is confirmed when serial titers of ASO rise over a period of weeks, then fall slowly. ASO titers peak during the third week after the onset of acute symptoms of a streptococcal disease; at six months after onset, approximately 30% of patients exhibit abnormal titers.

KEY TERMS

Antibody—A protein manufactured by a type of white blood cells called lymphocytes, in response to the presence of an antigen, or foreign protein, in the body. Because bacteria, viruses, and other organisms commonly contain many antigens, antibodies are formed against these foreign proteins to neutralize or destroy the invaders.

Antigen—A substance that can trigger a defensive response in the body, resulting in production of an antibody as part of the body's defense against infection and disease. Many antigens are foreign proteins not found naturally in the body, and include bacteria, viruses, toxins, and tissues from another person used in organ transplantation.

Glomerulonephritis—An inflammation of the glomeruli, the filtering units of the kidney. Damage to these structures hampers removal of waste products, salt, and water from the bloodstream, which may cause serious complications. This disorder can be mild and cause no symptoms, or so severe enough to cause kidney failure.

Rheumatic fever—A disease that causes inflammation in various body tissues. Rare in most developed countries, but reported to be on the increase again in parts of the United States. Joint inflammation occurs, but more serious is the frequency with which the disease permanently damages the heart. The nervous system may also be affected, causing Sydenham's chorea.

Sydenham's chorea—A childhood disorder of the central nervous system. Once called St. Vitus' dance, the condition is characterized by involuntary, jerky movements that usually follow an attack of rheumatic fever. Rare in the United States today, but a common disorder in developing countries. Usually resolves in two to three months with no long-term adverse effects.

Antideoxyribonuclease-B titer (anti-DNase B, or ADB)

Anti-DNase-B, or ADB, also detects antigens produced by group A strep, and is elevated in most patients with rheumatic fever and poststreptococcal glomerulonephritis. This test is often done concurrently with the ASO titer, and subsequent testing is usually performed to detect differences in the acute and convalescent blood samples. When ASO and ADB are performed concurrently, 95% of previous strep infections are detected. If both are repeatedly negative, the likelihood is that the patient's symptoms are not caused by a poststreptococcal disease.

When evaluating patients with acute rheumatic fever, the American Heart Association recommends the ASO titer rather than ADB. Even though the ADB is more sensitive than ASO, its results are too variable. It also should be noted that, while ASO is the recommended test, when ASO and ADB are done together, the combination is better than either ASO or ADB alone.

Streptozyme

The streptozyme test is often used as a screening test for antibodies to the streptococcal antigens NADase, DNase, streptokinase, streptolysin O, and hyaluronidase. This test is most useful in evaluating suspected poststreptococcal disease following *Streptococcus pyogenes* infection, such as rheumatic fever.

Streptozyme has certain advantages over ASO and ADB. It can detect several antibodies in a single assay, it is technically quick and easy, and it is unaffected by factors that can produce false-positives in the ASO test. The disadvantages are that, while it detects different antibodies, it does not determine which one has been detected, and it is not as sensitive in children as in adults. In fact, borderline antibody elevations, which could be significant in children, may not be detected at all. As with the ASO and ADB, a serially rising titer is more significant than a single determination.

Preparation

These tests are performed on blood specimens drawn from the patient's vein. The patient does not need to fast before these tests.

Risks

The risks associated with these tests are minimal but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after the blood is drawn, or blood accumulating under the puncture site (hematoma).

Results

Antistreptolysin O titer:

- adult: 160 Todd units/mL
- child: 6 months to 2 years: 50 Todd units/mL; 2 to 4 years: 160 Todd units/mL; 5 to 12 years: 170–330 Todd units/mL
- newborn: similar to the mother's value

Antideoxyribonuclease-B titer:

- adult: 85 units
- child (preschool): 60 units
- child (school age): 170 units

Streptozyme: less than 100 streptozyme units.

Abnormal results

Antistreptolysin O titer: Increased levels are seen after the second week of an untreated infection in acute streptococcal infection, and are increased with acute rheumatic fever, acute glomerulonephritis (66% of patients will not have high ASO titers), and scarlet fever.

Antideoxyribonuclease-B titer: Increased titers are seen in cases of acute rheumatic fever and post-streptococcal glomerulonephritis.

Streptozyme: As this is a screening test for antibodies to streptococcal antigens, increased levels require more definitive tests to confirm diagnosis.

Streptococcal infections

Definition

Streptococcal (strep) infections are communicable diseases that develop when bacteria of the genus *Streptococcus* invade parts of the body and overwhelm the body's immune system. Not every streptococcal infection causes detectable symptoms.

The scarlet fever rash on this person's arm was caused by a streptococcal infection. *(Custom Medical Stock Photo, Inc.)*

Description

Streptococcal bacteria produce symptoms that vary widely in location and severity—everything from skin infections to sore throats and **scarlet fever** to rare, but frequently fatal, necrotizing fasciitis and streptococcal toxic shock. Many people have some form of streptococcus bacteria in their body at some point in their life without necessarily showing any symptoms of infection. Nevertheless, a person who hosts bacteria without showing signs of infection is a carrier and can pass the infection on to others.

Types of infection

Primary strep infections invade healthy tissue. **Strep throat**, more formally called streptococcal pharyngitis, is the most common type of primary strep infection. It accounts for between 5–10% of all sore throats. and is especially common among school-aged children. Secondary strep infections invade tissue already weakened by injury or illness. Secondary strep infections frequently affect the bones, ears, eyes, joints, or intestines. Both primary and secondary strep infections can travel from affected tissues to lymph glands or enter the bloodstream and spread throughout the body (systemic infection). Many different strains of streptococcal bacteria have been identified since the 1930s. Types A, B, C, D, and G are the strains most likely to make people ill.

GROUP A *STREPTOCOCCUS*. All Group A strep (GAS) is the form of streptococcal bacteria most likely to be associated with serious illness. GAS is found worldwide. The incidence of respiratory strep A infections (strep throat, for example) is highest in cold climates and among young children. The incidence of GAS skin infections is highest in the tropics.

Two of the most severe invasive GAS infections are necrotizing fasciitis or flesh-eating bacteria disease, which causes the destruction of muscle tissue and fat, and **toxic shock syndrome**, a rapidly progressive disorder that causes shock and damages internal organs. In the mid-2000s, particularly virulent (strong and causing serious illness) strains of GAS bacteria appeared to be increasing. GAS is also the type of strep responsible for strep throat and scarlet **fever**. Strep throat is very common and is usually not serious. If untreated, however, strep throat can lead to **rheumatic fever**, which can permanently damage the heart and other organs.

GROUP B *STREPTOCOCCUS*. Group B strep (GBS) most often affects pregnant women, infants, the elderly, and chronically ill adults such as those with HIV/AIDS. Streptococcal infection occurs when bacteria contaminate cuts or open sores or otherwise penetrate the body's natural defenses. GBS exists in the reproductive tract of between 5 and 40% of all women. Most of these women are carriers who do not develop symptoms of infection. Nevertheless, they can transmit the bacterium to their newborns during **childbirth**. In the United States in 2006, two to three of every 1,000 live-born babies had a GBS infection. However, the number of babies dying of neonatal GBS infection has been declining steadily since the 1980s, most likely as the result of prevention programs initiated by the United States Centers for Disease Control (CDC).

About 75% of infected infants develop early-onset infection. Sometimes evident within a few hours of birth and always apparent within the first week of life, this condition causes inflammation of the membranes covering the brain and spinal cord (**meningitis**), **pneumonia**, blood infection (**sepsis**) and other problems.

Late-onset GBS develops between the ages of seven days and three months. It often causes meningitis. About half of all cases of this rare condition can be traced to mothers who are GBS carriers. The cause of the others is unknown.

Elderly individuals, especially those with other health problems, are also at higher risk of contracting a serious GBS infection that can spread to the entire body.

GROUP C *STREPTOCOCCUS*. Group C streptococcus (GCS) is a common source of infection in animals. It rarely causes human illness.

GROUP D *STREPTOCOCCUS*. Group D streptococcus (GDS) is a common cause of wound infections in hospital patients. GDS is also associated with:

- abnormal growth of tissue in the gastrointestinal tract
- urinary tract infection (UTI)
- uterine infections in women who have just given birth

GROUP G *STREPTOCOCCUS*. Normally present on the skin, in the mouth and throat, and in the intestines and genital tract, Group G strep (GGS) is most likely to lead to infection in alcoholics and in people who have cancer, **diabetes mellitus**, **rheumatoid arthritis**, and other conditions that suppress immune-system activity.

GGS can cause a variety of serious infections, including:

- bacteria in the bloodstream (bacteremia)
- inflammation of the connective tissue structure surrounding a joint (bursitis)
- endocarditis (a condition that affects the lining of the heart chambers and the heart valves)
- meningitis
- inflammation of bone and bone marrow (osteomyelitis)
- inflammation of the lining of the abdomen (peritonitis)

Causes and symptoms

Streptococcal infection occurs when bacteria contaminate cuts or open sores or otherwise penetrate the body's natural defenses.

GAS

GAS is transmitted by direct contact with saliva, nasal discharge, or open **wounds** of someone who has the infection. Chronic illness, **kidney disease** treated by dialysis, and steroid use increase vulnerability to infection.

About one of five people with GAS infection develops a sore, inflamed throat (strep throat), and pus on the tonsils. The majority of those infected by GAS either have no symptoms or develop enlarged lymph nodes, fever, **headache**, nausea, **vomiting**, weakness, and a rapid heartbeat.

Necrotizing fasciitis, also called flesh-eating bacteria disease, can be caused by a virulent strain of GAS. In this rare disease (only 500 cases have been reported since 1883), tissues become gangrenous and rapidly decompose from the interior outward to the skin, resulting in muscle and skin loss. The death rate is as high as 75%. Toxic shock syndrome is characterized by severe headache, **sore throat**, fever as high as 105°F (40.6°C), **dehydration**, watery **diarrhea**, and a sunburn-like rash that spreads from the face to the rest of the body. Symptoms develop suddenly and can be fatal.

GBS

A pregnant woman who has GBS infection can develop infections of the bladder, blood, and urinary tract, and deliver a baby who is infected or stillborn. The risk of transmitting GBS infection during birth is highest in a woman whose labor begins before the 37th week of **pregnancy** or lasts more than 18 hours or who:

- becomes a GBS carrier during the final stages of pregnancy
- has a GBS urinary-tract infection
- has already given birth to a baby infected with GBS
- develops a fever during labor

Among men, and in women who are not pregnant, the average age of infection with GBS is 64. African Americans appear to be significantly more susceptible to infection by this strain of strep than any other racial group. The most common consequences of GBS infection are pneumonia and infections of blood, skin, and soft tissue.

Miscellaneous symptoms

Other symptoms associated with strep infection include:

- anemia
- elevated white blood cell counts
- inflammation of the epiglottis (epiglottitis)
- heart murmur
- high blood pressure
- infection of the heart muscle
- kidney inflammation (nephritis)
- swelling of the face and ankles

Diagnosis

Strep bacteria can be obtained by swabbing the back of the throat, vagina, rectum, or the infected area with a sterile cotton swab. There are two types of tests to determine if a person has a strep infection. A rapid strep test uses material collected on a sterile swab from the throat or other area where strep is suspected. This test can be done in a doctor's office and can determine only the presence of streptococcal bacteria. It is most often used to determine if a person has strep throat. The results of a rapid strep test are available in about 20 minutes. The advantage of this test is the speed with which a diagnosis can be made.

The rapid strep test has a false negative rate of about 25%. In other words, in about one out of every four cases where no strep is detected by the rapid strep test, the patient actually does have a strep infection. Because of this, when a rapid strep test is negative, the doctor often does a culture test.

For a culture, a sample of swabbed material is grown in the laboratory on a medium that allows technicians to determine what kind of bacteria are present. Results take 24–48 hours. The test is very accurate and will show the presence of other kinds of bacteria besides *Streptococci*.

Treatment

Penicillin is often the antibiotic of choice to treat strep infections. Oral penicillin is usually taken for 10 days for infections such as strep throat and longer for systemic infections. Patients need to take the entire amount of antibiotic prescribed and not discontinue taking the medication when they feel better. Stopping the antibiotic early can lead to a return of the strep infection. Occasionally, a single injection of long-acting penicillin (Bicillin) is given instead of 10 days of oral treatment. It takes less than 24 hours for **antibiotics** to eliminate an infected person's ability to transmit strep bacteria.

About 10% of the time, penicillin is not effective against the strep bacteria. When this happens a doctor may prescribe other antibiotics such as cefuroxime (Ceftin), cefixime (Suprax), cefpodoxime proxetil (Vantin), loracarbef (Lorabid), cefditoren (Spectracef), azithromycin (Zithromax), clindamycin (Cleocin), or a cephalosporin (Keflex, Durocef, Ceclor). Erythromycin (Eryzole, Pediazole, Ilosone), another inexpensive antibiotic, can be given to people who are allergic to penicillin. Scarlet fever is treated with the same antibiotics as strep throat.

Without treatment, the symptoms of untreated strep throat begin subsiding in four or five days. However it is important to treat strep infections promptly with antibiotics because of the possibility of developing secondary disorders or infections. For example, rheumatic fever and rheumatic **heart disease** may develop from untreated strep throat.

Guidelines developed by the American Academy of Obstetrics and Gynecology (AAOG), the American Academy of Pediatrics (AAP), and the Centers for Disease Control and Prevention (CDC) recommend administering intravenous antibiotics to a woman at high risk of passing GBS infection on to her child, and offering the medication to any pregnant woman who wants it.

Initiating antibiotic therapy at least four hours before birth allows medication to become concentrated

enough to protect the baby during its passage through the birth canal.

Newborns infected with GBS during or shortly after birth may die. Those who survive can require lengthy hospital stays and may develop vision or **hearing loss** and other permanent disabilities.

Alternatives

Conventional medicine is very successful in treating strep infections. However, several alternative therapies, including homeopathy and botanical medicine, may help relieve symptoms or support the person with a strep infection. For example, several herbs, including garlic (*Allium sativum*), **echinacea** (*Echinacea* spp.), and goldenseal (*Hydrastis canadensis*), are believed to strengthen the immune system, thus helping the body fight a current infection, as well as helping prevent future infections.

Prognosis

Most people who develop strep infections are treated with antibiotics and recover promptly without complications. Strep throat, for example, is almost never fatal. However, GAS is that results in systemic (involving the whole body) infection has a death rate of 25–40%. Streptococcal toxic shock and necrotizing fasciitis also have high death rates. GBS infection can be fatal in newborns and the elderly.

Prevention

Exposure to infected people should be avoided. However, the risk of getting one or passing one on to another person can be minimized by:

- washing hands well and frequently, especially after nose blowing or sneezing and before food handling
- disposing of used tissues properly
- avoiding close contact with someone who has a strep throat
- not sharing food and eating utensils with anyone
- not smoking

Stress

Definition

Stress is defined as an organism's total response to environmental demands or pressures. When stress was first studied in the 1950s, the term was used to denote both the causes and the experienced effects of these pressures. More recently, however, the word stressor has been used for the stimulus that provokes a stress response.

Description

Stress in humans results from interactions between persons and their environment that are perceived as straining or exceeding their adaptive capacities and threatening their well being. The element of perception indicates that human stress responses reflect differences in personality as well as differences in physical strength or general health. One recurrent disagreement among researchers concerns the definition of stress in humans. Is it primarily an external response that can be measured by changes in glandular secretions, skin reactions, and other physical functions, or is it an internal interpretation of, or reaction to, a stressor; or is it both?

Risk factors

Risk factors for stress-related illnesses are a mix of personal, interpersonal, and social variables. These factors include lack or loss of control over one's

physical environment and lack or loss of social support networks. People who are dependent on others (e.g. children or the elderly) or who are socially disadvantaged (because of race, gender, educational level, or similar factors) are at greater risk of developing stress-related illnesses. Other risk factors include feelings of helplessness, hopelessness, extreme fear or anger, and cynicism or distrust of others.

Recent research indicates that some vulnerability to stress is genetic. Scientists at the University of Wisconsin and King's College London discovered that people who inherited a short, or stress-sensitive, version of the serotonin transporter gene were almost three times as likely to experience depression following a stressful event as people with the long version of the gene. Further research is likely to identify other genes that affect susceptibility to stress.

Demographics

Most people experiences stress in their lives at some time. One study found that about 75% of those surveyed reported experiencing at least some stress in the previous two weeks. Occasional stress is an expected part of life for most people, and while often unpleasant, does not lead to long-term negative outcomes. In some cases however, severe or prolonged stress can lead to illness.

Causes and symptoms

Causes

The causes of stress can include any event or occurrence that a person considers a threat to his or her coping strategies or resources. Researchers generally agree that a certain degree of stress is a normal part of a living organism's response to the inevitable changes in its physical or social environment, and that positive, as well as negative, events can generate stress. Stress-related disease, however, results from excessive and prolonged demands on an individual's coping resources.

Stress can come from many different situations or events, and can affect different people in different ways. Things that cause stress in one individual may not cause a negative response in another individual. A specific upcoming event can cause significant stress, such as an upcoming job interview, presentation, or final exam. Even upcoming events that are considered positive or exciting can cause stress, such as a wedding or the birth of a baby. When an upcoming event is the source of stress, the individual may experience a constant, nagging worry about the event. The person may visualize the event repeatedly, and may worry about things that could go wrong. It is often hard to stop thinking about the event. This type of stress can take a significant toll when it persists over long periods of time.

Stress also may be caused by things going on in the world. Events such as the terrorist attacks of September 11th, 2001 are believed to have increased stress in people not only in the United States, but also around the world. Events like terrorist attacks can lead to worry about the safety of family members and loved ones, worries about when another attack may happen, or concerns about many other things. These kind of worries, when they occur over a long period of time, can lead to stress and related negative outcomes.

A traumatic event, such as a car accident, earthquake, rape, or even witnessing a traumatic event, can cause severe stress. In these cases an individual may mentally relive the event repeatedly. This is a normal response to a traumatic event but if it persists for more than a short time or does not seem to be getting better, the individual may have **post-traumatic stress disorder** (PTSD), a serious psychiatric illness that occurs in individuals who have participated in or witnessed traumatic events. PTSD is particularly common as among warfighters who are constantly under stress while engaged in military campaigns.

Stress also can be caused, not just by a single event, but also by the presence of issues and problems that are upsetting or frustrating in day-to-day life. These can include worries about money, pressure at work, and problems with a relationship. Events such as divorce or the death of a loved one can also cause stress for many months or years.

Symptoms

The symptoms of stress can be either physical or psychological or both. Physical symptoms may include

problems sleeping, **indigestion**, stomach pains, chest pains, **fatigue**, **headache**, back or neck **pain**, and many others. Psychological signs of stress include **anxiety**, frustration, irritability, and even depression. These symptoms may not be problematic if they occur for a short period of time but if they are ongoing an individual should consider seeing a doctor.

Stress-related physical illnesses, such as **irritable bowel syndrome**, heart attacks, arthritis, and chronic headaches, can result from long-term overstimulation of a part of the nervous system that regulates the heart rate, blood pressure, and digestive system. Stress-related emotional illness results from inadequate or inappropriate responses to major changes in one's life situation, such as marriage, completing one's education, becoming a parent, losing a job, or retirement. Psychiatrists sometimes use the term "adjustment disorder" to describe this type of illness. In the workplace, stress-related illness often takes the form of burnout—a loss of interest in or ability to perform one's job due to long-term high stress levels. For example, **palliative care** nurses are at high risk of burnout due to their inability to prevent their patients from dying or even to relieve their physical suffering in some circumstances.

Diagnosis

When the doctor suspects that a patient's illness is connected to stress, the doctor will take a careful history that includes stressors in the patient's life (e.g. family or employment problems, other illnesses, recent major life changes). Many physicians will evaluate the patient's personality as well, in order to assess his or her coping resources and emotional response patterns. There are several personality inventories and **psychological tests** that doctors can use to help diagnose the amount of stress their patients experience and the coping strategies they use in dealing with them. A variation on this is to identify what the patient perceives as threatening as well as stressful. Stress-related illness can be diagnosed by primary care doctors, as well as by those who specialize in psychiatry. The doctor will need to distinguish between **adjustment disorders** and anxiety or **mood disorders**, and between psychiatric disorders and physical illnesses (e.g., abnormal thyroid activity) that have psychological side effects.

Treatment

Recent advances in the understanding of the many complex connections between the human mind and body have produced a variety of mainstream approaches to stress-related illness. Present treatment regimens may include one or more of the following:

- Medications. These may include drugs to control blood pressure or other physical symptoms of stress, as well as drugs that affect the patient's mood (tranquilizers or antidepressants).
- Stress management programs. These may be either individual or group treatments, and usually involve analysis of the stressors in the patient's life. They often focus on job or workplace-related stress.
- Behavioral approaches. These strategies include relaxation techniques, breathing exercises, and physical exercise programs including walking.
- Massage. Therapeutic massage relieves stress by relaxing the large groups of muscles in the back, neck, arms, and legs.
- Cognitive therapy. These approaches teach patients to reframe or mentally reinterpret the stressors in their lives in order to modify the body's physical reactions.

KEY TERMS

Adjustment disorder—A psychiatric disorder marked by inappropriate or inadequate responses to a change in life circumstances. Depression following retirement from work is an example of adjustment disorder.

Biofeedback—A technique in which patients learn to modify certain body functions, such as temperature or pulse rate, with the help of a monitoring machine.

Burnout—An emotional condition, marked by tiredness, loss of interest, or frustration, that interferes with job performance,. Burnout is usually regarded as the result of prolonged stress.

Stress hardiness—A personality characteristic that enables persons to stay healthy in stressful circumstances. It includes belief in one's ability to influence the situation; being committed to or fully engaged in one's activities; and having a positive view of change.

Stress management—A category of popularized programs and techniques intended to help people deal more effectively with stress.

Stressor—A stimulus, or event, that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

WWW.BOOKBAZ.IR

- Meditation and associated spiritual or religious practices. Recent studies have found positive correlations between these practices and stress hardiness.

Alternatives

Treatment of stress is one area in which the boundaries between traditional and alternative therapies have changed in recent years, in part because some forms of physical **exercise** (**yoga**, tai chi, aikido) that were once associated with the counterculture have become widely accepted as useful parts of mainstream **stress reduction** programs. Other alternative therapies for stress that are occasionally recommended by mainstream medicine include **aromatherapy**, dance therapy, **biofeedback**, nutrition-based treatments (including **dietary guidelines** and **nutritional supplements**), **acupuncture**, homeopathy, and herbal medicine.

Prognosis

The prognosis for recovery from a stress-related illness is dependent on a wide variety of factors in a person's life, many of which are genetically determined (e.g. race, sex, illnesses that run in families) or beyond the individual's control (e.g. economic trends, cultural stereotypes and prejudices, death of a loved one). It is possible, however, for an individual to learn new responses to stress and, thus, change their experiences of it. A person's ability to remain healthy in stressful situations is sometimes referred to as stress hardiness. Stress-hardy people have a cluster of personality traits that strengthen their ability to cope. These traits include believing in the importance of what they are doing; believing that they have some power to influence their situation; and viewing life's changes as positive opportunities rather than as threats.

Prevention

Complete prevention of stress is neither possible nor desirable because stress is an important stimulus of human growth and creativity, as well as an inevitable part of life. In addition, specific strategies for stress prevention vary widely from person to person, depending on the nature and number of the stressors in an individual's life, and the amount of control that person has over these factors. In general, however, a combination of attitudinal and behavioral changes works well for most patients. An important form of prevention may be parental modeling of healthy attitudes and behaviors within the family.

Stress reduction

Definition

Stress is the body's normal response to anything that disturbs its natural physical, emotional, or mental balance. Stress reduction refers to various strategies that counteract this response and produce a sense of relaxation and tranquility.

Purpose

Although stress is a natural phenomenon of living, stress that is not controlled and that continues for a long period of time can seriously compromise health. For this reason, stress must be understood, managed, and appropriately reduced. Several very different strategies and therapies are available that can help with relaxation and stress management.

Precautions

Stress reduction can only present a problem if an individual attributes an actual, serious condition or disease to being simply a stress-related response and avoids consulting a physician.

People who have undergone a severe **trauma** (criminal assault, combat, natural disaster, car accident, etc.) may experience symptoms of **post-traumatic stress disorder** (PTSD) or **acute stress disorder** (ASD). These disorders are defined by their temporal connection to a traumatic event in the patient's life, and are characterized by a cluster of **anxiety** and dissociative symptoms. They interfere with the patient's normal level of functioning, and require some form of supportive therapy. People who experience a sense of detachment or unreality, emotional numbing, a general feeling of being dazed, **amnesia** for part of the traumatic event, or similar symptoms should consult a medical doctor in addition to using other approaches to stress reduction.

Description

Everyone encounters stress every day. Although most people think of stress as negative, it is neither good nor bad but is neutral or nonspecific. Stress may be internal (from within ourselves) or external (such as noise from the environment) and does not always result from something unpleasant. Stress can also be caused by events that are positive, like an upcoming wedding or the birth of a child. A certain amount of stress is actually essential to being sufficiently stimulated to meet the challenges of everyday life, but when stress is constant and acute, it can have dangerous consequences.

The specific and immediate cause of stress is called the stressor. A stressor can be something dramatic or terrible, such as a violent experience or the death of a loved one, or it can be a positive and rewarding event, like marriage or a promotion. The stressor can be internal, such as feelings of guilt or anger felt in a relationship, or it can be external, such as a natural disaster or the ordinary rigors and frustrations of commuting. It can also have a physical source, like simple **exercise** or hard work, or it can be strictly mental, like worry. Our bodies react the same way physiologically no matter what the source of the stress.

From a physical standpoint, the body reacts to stress in a standard and predictable manner. When stress occurs, the brain immediately receives nerve impulses. These impulses initiate an automatic sequence carried out by the body's sympathetic nervous system: it begins with stimulation of the brain's hypothalamus, which sends nerve impulses to both the adrenal and the pituitary glands. Also called the "fight or flight" response, this automatic physiological process is known to have evolved in humans and animals to enable them to cope with sudden, life-threatening emergencies. When faced with a major stressor, the body's **biochemistry** instantly hurtles into a ready mode that marshals all the possible resources necessary to either escape or do battle. Thus, the adrenal glands located on top of the kidneys provide an instant surge of adrenaline, quickening the heart rate and blood flow and providing every cell with extra oxygen. They also relea se cortisol or hydrocortisone, causing an increase in both amino acids (the building blocks of proteins) and blood sugar. These are required for tissue repair to take place. Finally, the pituitary gland at the base of the brain releases a variety of hormones, including endorphins, that act as natural painkillers and permit the body to do things it ordinarily could not do. Thus, very shortly after a stressor is recognized by the body, the heart and breathing rate spike, the pupils dilate to improve vision, perspiration increases, digestion slows, and the body is aroused, energized, and temporarily has an increased threshold for **pain**. This sequence of events allows individuals to do whatever is required to save themselves, whether it is to flee from a predator or engage in combat and fend off an attack.

While these automatic physiological responses served early humans well and were essential to survival of the species, today's men and women rarely must literally fight for their lives or dodge and elude a predator. Yet the body's automatic response to stress has remained largely unchanged in a radically changed world. Whether caveman or corporate executive, when the fight-or-flight response kicks in, a three-stage process begins. Stage one is the alarm stage in which the body releases hormones and prepares for extreme physical action. Resistance is stage two in which the body attempts to resist yet adapt to the stress and to repair any damage done. The final stage, exhaustion, occurs if the stress remains constant. It is especially dangerous since stage one's physical response may begin all over again. The persistence of stress and stage three's exhaustion is the point at which disease can occur. The body may then experience severe debilitating conditions like migraine, heart irregularities, and mental illness. Some bodily functions may even shut down altogether.

Although different individuals may have different levels of stress tolerance, chronic stress will eventually wear down even the strongest of people. Prolonged

WWW.BOOKBAZ.IR

stress can cause biochemical imbalances that weaken the immune system and invite serious illness. Overall, stress that persists is known to interfere with digestion and, more seriously, alter brain chemistry, create hormonal imbalances, increase heart rate, raise blood pressure, and negatively affect both metabolic and immune function. It is also important to recognize that although stress itself is not a disease, it can worsen any number of already serious physical conditions. While long-term stress can seriously affect one's quality of life and lead to major, sometimes fatal, diseases, prolonged stress also results in the everyday miseries of **headache** and allergy, digestive disorders and **fatigue**, irritable bladder and **impotence**, **insomnia**, anxiety, depression, and chronic aches and pains. Researchers explo ring the connection between stress and susceptibility to colds exposed stressed individuals (who had experienced a death in the family, become divorced, or had recently moved) to cold viruses and then tested for antibodies a month later. Results indicated that severely stressed individuals were four times more likely to become infected.

Stress can cause or contribute to illness but reducing stress may have the opposite effect and may strengthen the body and even encourage healing. The most important step toward reducing the stress may be to understand the nature of stress and to learn how to gain some control over it. Being able to recognize that one is stressed is the first step in reducing stress. Of the many signs and symptoms that indicate the presence of stress, some are obvious and require only common sense to recognize. Short-term noticeable effects of stress include sweaty palms and other types of perspiration, dilated pupils, and difficulty in swallowing ("a lump in the throat"). Tightness in the chest is another stress signal as are stomach problems and some skin conditions. Stress that is the result of prolonged anxiety (a sense of apprehension) often results in feelings of panic or actual trembling, fatigue, insomnia, and **shortness of breath**, heart **palpitations** and **dizziness**, and irritability. Although none of these symptoms is pleasant, they are relatively minor compared to the silent but much more serious internal effects that can lead to serious health problems.

Fortunately, stress and the negative effects it creates can be reduced by a wide variety of therapeutic approaches. When successfully applied, many of these therapies and strategies can both reduce stress and begin reverse its damage. Before selecting a particular therapy, it is important to be able to distinguish unhealthy stress from stress that is not negative. Researchers have found that the most important variable among types of stress is an individual's sense of control over the situation. The least harmful stress scenario is one in which an individual feels sufficient control and sense the situation is predictable. Put simply, predictable pain is less stressful because individuals know when to relax (gaining relief from pain as well as protecting themselves from its damaging effects). But when individuals have no warning of pain, they are in a state of constant stress. An example from daily life might be the difference between the stress experienced during a move by parents, who are in control and making decisions, and a child who does not have a say in the matter. The former can pick and choose when to enter or engage a stressful situation or problem but the latter has no control nor any ability to predict when such a situation will arise and are constantly on alert or in a state of anxiety.

For those with little control over situations that make them anxious, there are two ways to deal with the stress. One is to remove or reduce the stressor, and the other is to increase resistance to it. Although there are many strategies to achieve each of these, all of them can be reduced to some variation of a single simple concept—relaxation. While there is no one single technique or therapy that will help everyone, the combination of lifestyle change, diet, exercise, and relaxation will allow nearly all types of individuals to better manage the stress in their lives. Although relaxation is at the core of most stress reduction methods, it is not something that everyone can fully achieve without assistance and guidance.

There are a number of relaxation therapies that enable individuals to achieve deep, beneficial relaxation. These therapies can be grouped into the following general categories: mind-body therapies, body work and movement therapies, and herbal-based **diets** and natural regimens. Many of the specific techniques in these categories can be part of a self-help or self-care approach, although some require the help of an experienced practitioner.

Therapies that focus on a connection between the mind and body are based on the fact that thinking patterns and emotions can have physical effects on the body. These techniques encourage the individual to take control and learn techniques for coping with stressors rather than trying to eliminate them. Such therapies range from individual counseling and **meditation** or involvement with a support group to **guided imagery** and **biofeedback**. They all have the common goal of evoking the physiological relaxation response in which a person can achieve beneficial internal

results such as lowering blood pressure and decreasing gastric acid secretion.

Body work and movement therapies include techniques ranging from dance therapy and massage to **reflexology** and **rolfing**. Body work is based partly on the therapeutic power of human touch and can also include manipulation, realignment, and posture correction. Movement therapies are a particular form of physical exercise, although they attempt to do much more than simply get a person into shape. Most usually emphasize the mind/body connection and strive to put people in better touch with both their bodies and their feelings. Body work and movement therapies can be as vigorous as deep tissue manipulation or as simple and minimal as the Alexander technique's light posture corrections.

Herbal remedies for stress are usually part of a larger system of natural, **holistic medicine**. Whether Chinese traditional medicine, its counterpart from India, or the homeopathy of the West, all these systems of natural medicine have a holistic focus and emphasize the need for inner balance. All demonstrate how the individual's physical, emotional, mental, and spiritual states are connected and use natural substances as part of the treatment for reducing stress. Such therapies range from the occasional purging (cleansing) of **Ayurvedic medicine** to the sleep-inducing properties of chamomile tea. They also can include the use of cayenne to relieve pain, fragrant essential oils from flowers to evoke a pleasing response and relieve tension, or aloe vera to soothe burned skin.

Some of the more common therapies and techniques available for reducing stress include:

- Acupuncture. Insertion of needles at certain spots under the skin for the purpose of attaining balance by either releasing blocked energy or draining off excess energy.
- Alexander technique. Improving the alignment of head, neck, and back to achieve efficient posture and movement.
- Aromatherapy. Massage with essential oils from flowers to affect mood and produce a sense of well-being.

- Bach flower therapy. Herbal remedies that are prepared from flowers acting energetically to soothe the mind and body.
- Bioenergetics. A practice that encourages sudden release of tensions by crying or kicking.

- Feldenkrais method. Slow, light movements alter habits and reeducate neuromuscular system.
- Flotation therapy. Floating in a soundproof tank with no external stimulation.
- Guided imagery. Creating a mental picture of what is desired. Also called Creative imagery or Visualization.
- Herbal medicine. Uses substances derived from plants as treatment instead of synthetic drugs.
- Homeopathy. Uses minute doses of plant, animal, and mineral substances to stimulate the body's natural healing.
- Hydrotherapy. Use of water internally and externally for healing purposes.
- Hypnotherapy. Hypnosis in order to identify and release patterns that keep an individual from a personal balance point.
- Kinesiology. Uses muscle testing to correct imbalances in the body's "energy system." Also called Touch for Health.
- Massage. Use of touch and manipulation to soothe. Can also employ vigorous deep tissue manipulation.
- Meditation. Deep, relaxed, receptive, and focused concentration on a single object, sound, or word.
- Music therapy. Playing or listening to music to create an emotional reaction.
- Naturopathy. A complete healthcare system that uses a variety of natural healing therapies.
- Psychotherapy. A talking-based therapy with a mental health professional to get at the root of

a conflict, modify behavior or change disruptive thought patterns.

- Reflexology. Manipulation of zones of the feet that relate to the major organs, glands, and areas of the body.
- Rolfing. Vigorous manipulation of the body's connective tissue to restore "balance."
- Shiatsu. Traditional Japanese finger pressure massage therapy.
- Sound therapy. Uses sound waves to slow the body's autonomic system.
- Tai chi chuan. System of slow, continuous exercises based on rhythm and equilibrium.
- Yoga. System of exercises that combines certain positions with deep breathing and meditation.

These and many other techniques, systems, and therapies are available to the person seeking to reduce and manage stress. Some methods are very simple and can be easily learned, while others are high-tech and often involve a practitioner. A search for common elements among most of these stress-reducing systems reveals several strategies that many people may be able to employ on their own. However, it is important to know and recognize the signals of stress. Further, it is easier to resist the negative effects of stress by eating properly and getting sufficient sleep and exercise.

Nearly all stress-reducing systems are geared to evoking some degree of beneficial mind/body relaxation and most include some version of the following:

- mental time out
- deep breathing
- meditation and singular focus
- gentle, repetitive exercise

The best stress reduction system is the one that works for the individual. Whether stress can be relieved by laughter, mellow music, repetition of a single word, self-massage, vigorous activity, or simply by doing everyday chores in a mindful state of heightened awareness, it is important that stress be recognized and managed every day. Studies have shown that regular relaxation eventually makes the body less responsive to its stress hormones and acts as a sort of natural tranquilizer. It is as if people can build their own defense against the stress response.

Many companies have introduced workplace stress management programs to improve their employees' health. These programs typically include instruction on emotional refocusing or restructuring, and have been shown to be beneficial in reducing the participants' blood pressure, heart rate, and other signs of emotional upset. In addition, stress management programs designed for persons in specific high-stress occupations (medicine, law enforcement, emergency response, etc.) have proved to be effective in reducing burnout and helping members of these professions cope with the specific stresses of their respective jobs.

An additional general strategy for handling stress in family life or the workplace is the cultivation of a group of character traits that has been termed "psychological hardiness." These traits include believing in the importance of what one is doing, believing that one has some power to influence the immediate situation, and viewing life's changes as positive opportunities rather than as threats. These qualities are sometimes referred to as the "3 Cs," which stand for commitment, control and challenge. Approaches to stress reduction that enhance these qualities are especially beneficial.

One trend in stress reduction is the development of stress management programs or stress reduction strategies tailored to specific categories of people, often defined by their occupation or by a chronic health condition. For example, journalists who cover traumatic events were increasingly recognized as susceptible to developing posttraumatic stress disorder. In July of 2007 a study presented at the annual meeting of the American Society for Clinical Oncology showed men taught stress management techniques before surgery for **prostate cancer** had improved outcomes after both 6 and 12 months.

Another trend in stress reduction was the development of programs designed for communities as well as individuals. After the events of September 11, 2001, many mental health professionals recognized that acts of terrorism or mass violence affect large groups of people and that psychiatric interventions need to address stress as a group experience as well as an individual one.

Risks

All relaxation-based therapies to reduce stress are generally considered free of risk.

Results

Learning how to manage stress has the short-term benefits of giving people some sense of control in their lives, providing them with positive coping strategies, and making them more relaxed and healthier. The long-term benefits can be a stronger immune system, proper hormonal balance, and reduced susceptibility to disease.

Stress test

Definition

A **stress** test is primarily used to identify **coronary artery disease**. Consequently, it is also sometimes called a cardiac stress test or cardiac diagnostic test. The stress test measures the ability of the heart to react to **exercise** while being monitored in a controlled environment. The test measures the heart at rest and while it is under the stress of exercise. It requires patients to exercise on a treadmill or exercise bicycle while their heart rate, blood pressure, electrocardiogram (ECG), and any symptoms that occur during the test are monitored. The result shows the general physical condition of their circulatory system and, specifically, may show when an abnormal flow of blood is going into or out of the heart. Besides helping to diagnose **heart disease**, it also provides prognoses after heart attacks.

Purpose

The body requires more oxygen during exercise than when it is at rest. To deliver more oxygen during exercise, the heart has to pump more oxygen-rich blood. Because of the increased stress on the heart, exercise can reveal coronary problems that are not apparent when the body is at rest. This is why the stress test, though not perfect, remains the best initial, noninvasive, practical coronary test.

The stress test is particularly useful for detecting ischemia (inadequate supply of blood to the heart muscle) caused by blocked coronary arteries. Less commonly, it is used to determine safe levels of exercise in people with existing coronary artery disease. A stress test may also be given when the following conditions are suspected or present:

- acute chest pain
- acute coronary syndrome (ACS)
- angina
- atypical or non-cardiac chest pain
- cardiac disease (if undergoing emergency non-cardiac surgery)
- coronary artery disease (if disease status changes)
- past coronary revascularization
- newly diagnosed heart failure or cardiomyopathy
- select arrhythmias
- valvular heart disease

Description

A technician affixes electrodes to the patient's chest, using adhesive patches with a special gel that conducts electrical impulses. Typically, electrodes are placed under each collarbone and each bottom rib, and six electrodes are placed across the chest in a rough outline of the heart. Wires from the electrodes are connected to an ECG, which records the electrical activity picked up by the electrodes.

The technician performs resting ECG tests while the patient is lying down, then standing up, and then breathing heavily for half a minute. These baseline tests can later be compared with the ECG tests performed while the patient is exercising. The patient's blood pressure is taken and the blood pressure cuff is left in place so that blood pressure can be measured periodically throughout the test.

The patient begins riding a stationary bicycle or walking on a treadmill. Gradually the intensity of the exercise is increased. For example, if the patient is walking on a treadmill, then the speed of the treadmill increases and the treadmill is tilted upward to simulate an incline. If the patient is on an exercise bicycle, then the resistance or "drag" is gradually increased. The patient continues exercising at increasing intensity until reaching the target heart rate (generally set at a minimum of 85% of the maximal predicted heart rate based on the patient's age) or experiencing severe **fatigue**, **dizziness**, or chest **pain**. During the test, the patient's heart rate, ECG, and blood pressure are monitored.

Sometimes other tests, such as **echocardiography** or thallium scanning, are used in conjunction with the exercise stress test. This is partly because studies suggest that women have a high rate of false negatives (results showing no problem when one exists) and false positives (results showing a problem when one does not exist) with the stress test. They may benefit from another test, such as exercise echocardiography. People

who are unable to exercise may be injected with drugs, such as adenosine, which mimic the effects of exercise on the heart, and then they are given a thallium scan. The thallium scan and echocardiogram are particularly useful when the patient's resting ECG is abnormal. In such cases, interpretation of exercise-induced ECG abnormalities is difficult.

An echocardiogram stress test is performed in a similar fashion to an ECG stress test (the subject rides a bike or walks on a treadmill in both tests). However, in an echocardiogram, sound waves create a moving image of the heart. The image is more detailed than the one produced with an x-ray scan and does not require radiation. The type of echocardiogram that is most often used is a transthoracic echocardiogram (TTE). In the TTE process, a transducer is positioned above or around the heart so that when high-frequency sound waves are emitted, the transducer receives back the sound waves as they bounce off the heart. The waves are transmitted as electrical impulses to the echocardiograph machine, which converts these impulses into two-dimensional or three-dimensional images of the heart. In addition to this, a Doppler echocardiogram records the motion of blood as it passes through the heart.

Radionuclide myocardial perfusion imaging (rMPI) is a nuclear procedure used in medicine that shows the function of the heart muscle. This imaging scan is the most common nuclear medicine procedure used for heart analyses. The scan is performed after a small amount of radioactive material such as thallium (chemical symbol Tl) or technetium (Tc) is injected into a vein of the patient. The radioactive material passes into the patient's heart muscle and images are taken with a special camera to obtain a three-dimensional image. In order to detect coronary heart disease, a stress test is performed along with the scan. The overall test requires two sets of images of the heart and usually two sets of injections. One set of images is obtained immediately after a patient exercises on a treadmill or after stressing the heart with a medication, and the other is taken while the heart is at rest.

The use of rMPI with single-photon emission computed tomography (SPECT) or **positron emission tomography** (PET) is well established for the diagnosis of coronary heart disease. SPECT is a nuclear medicine tomographic imaging technique that uses gamma rays to detect the functioning of the heart. In SPECT, a three-dimensional image is produced, one that consists of cross-sectional slices of an organ. PET, also a nuclear medicine tomographic technique, produces three-dimensional images by detecting pairs of gamma rays emitted indirectly by a radionuclide (called a tracer) that gives off tiny positively charged particles (positrons). A camera records the positrons and converts the recording into images on a computer. The tracer is introduced into the body at the beginning of the test. The PET scan is especially useful for determining the flow of blood in and around the heart.

Although exercise stress testing is generally preferred when evaluating the heart, an alternative means of evaluation is sometimes used in patients who cannot properly exercise for the test. The pharmacologic stress test is the evaluation method that does not use exercise as part of its method. It is most often used when patients cannot exercise to an adequate level, which is defined as at least 80% of the workload necessary for their gender and age, or 85% or more of their maximum heart rate for their gender and age.

Preparation

Patients are usually instructed not to eat or smoke for several hours before the test. They should be advised to inform the physician about any medications they are taking, and to wear comfortable sneakers and exercise clothing.

Patients should understand the purpose of the test and the signs and symptoms that indicate the test should be stopped. Physicians, nurses, and ECG technicians can ensure patients are safe by encouraging them to immediately communicate discomfort at any time during the stress test.

Aftercare

After the test, patients should rest until their blood pressure and heart rate return to normal. If all goes well, and there are no signs of distress, patients may return to their normal daily activities.

Risks

There is a very slight risk of myocardial infarction (a **heart attack**) from the exercise, as well as cardiac arrhythmia (irregular heartbeat), **angina**, or cardiac arrest (about one in 100,000). For this reason, exercise stress tests should be attended by healthcare professionals with immediate access to defibrillators and other emergency equipment.

Patients are cautioned to stop the test should they develop any of the following symptoms:

- unsteady gait
- confusion
- skin that is grayish or cold and clammy

WWW.BOOKBAZ.IR

- dizziness or fainting
- a drop in blood pressure
- angina (chest pain)
- cardiac arrhythmia (irregular heartbeat)

Results

A normal result of an exercise stress test shows normal electrocardiogram tracings and heart rate, blood pressure within the normal range, and no angina, unusual dizziness, or **shortness of breath**.

A number of abnormalities may appear on an exercise stress test. Examples of exercise-induced ECG abnormalities are ST segment depression or heart rhythm disturbances. These ECG abnormalities may indicate deprivation of blood to the heart muscle (ischemia) caused by narrowed or blocked coronary arteries. Stress test abnormalities generally require further diagnostic evaluation and therapy.

The Duke Treadmill Score (DTS) is a common prognostic scoring system used for finding a result from a stress test in which a patient has chest pain and is undergoing a treadmill stress test. It predicts coronary heart disease, but is not applicable for patients who already have coronary heart disease. The DTS is a weighted index that incorporates exercise duration, symptoms, and ECG changes based on the following:

- Treadmill Exercise Time (Ex Time): amount of time for treadmill exercise, using the standard Bruce protocol, in minutes, usually from 0 to 15 minutes
- Maximum net ST segment deviation (Max ST): taking into account depression or elevation, in millimeters after 80 milliseconds from the J-Point; usually 0 to 7 millimeters; the ST segment on an electrocardiogram connects the QRS complex and the T wave, and has a duration of 0.080 seconds to 0.120 seconds
- Exercise-induced Treadmill Angina Index (Angina Index): 0 (no angina during exercise), 1 (non-limiting), or 2 (exercise-limiting)

The scoring for DTS consists of the following equation: (treadmill exercise time) minus (five times maximum net ST deviation) minus (four times treadmill angina index); or (Ex Time) − (5 × Max ST) − (4 × Angina Index). A range of scores for the DTS is from −25 to −11 (for highest risk of coronary heart disease), −10 to +4 (moderate risk), and +5 to +15 (lowest risk).

Stridor

Definition

Stridor is a term used to describe noisy breathing in general and to refer specifically to a high-pitched crowing sound associated with **croup**, respiratory infection, and airway obstruction.

Description

Stridor occurs when erratic air currents attempt to force their way through breathing passages narrowed by:

- illness
- infection
- the presence of foreign objects
- throat abnormalities

Stridor can usually be heard from a distance but is sometimes audible only during deep breathing. Someone who has stridor may crow and wheeze when:

- inhaling
- exhaling
- inhaling and exhaling

Most common in young children, whose naturally small airways are easily obstructed, stridor can be a symptom of a life-threatening respiratory emergency.

Causes and symptoms

During childhood, stridor is usually caused by infection of the cartilage flap (epiglottis) that covers the opening of the windpipe to prevent **choking** during swallowing. It can also be caused by a toy or other tiny object the child has tried to swallow.

Laryngomalacia is a common cause of a rapid, low-pitched form of stridor that may be heard when a baby inhales. This harmless condition does not require medical attention. It usually disappears by the time the child is 18 months old.

The most common causes of stridor in adults are:

- abscess or swelling of the upper airway
- paralysis or malfunction of the vocal cords
- tumor

Other common causes of stridor include:

- enlargement of the thyroid gland (goiter)
- swelling of the voice box (largyngeal edema)
- narrowing of the windpipe (tracheal stenosis)

When stridor is caused by a condition that slowly narrows the airway, crowing and **wheezing** may not develop until the obstruction has become severe.

Diagnosis

When stridor is present in a newborn, pediatricians and neonatologists look for evidence of:

- heart defects inherent at birth (congenital)
- neurological disorders
- general toxicity

If examinations do not reveal the reasons for the baby's noisy breathing, the air passages are assumed to be the cause of the problem.

Listening to an older child or adult breathe usually enables pediatricians, family physicians, and pulmonary specialists to estimate where an airway obstruction is located. The extent of the obstruction can be calculated by assessing the following characteristics of the patient:

- complexion
- chest movements
- breathing rate
- level of consciousness

X rays and direct examination of the voice box (larynx) and breathing passages indicate the exact location of the obstruction or inflammation. Flow-volume

WWW.BOOKBAZ.IR

loops and pulse oximetry are diagnostic tools used to measure how much air flows through the breathing passages, and how much oxygen those passages contain.

Pulmonary function tests may also be performed.

Treatment

The cause of this condition determines the way it is treated.

Life-threatening emergencies may require:

- the insertion of a breathing tube through the mouth and nose (tracheal intubation)
- the insertion of a breathing tube directly into the windpipe (tracheostomy)

Stroke

Definition

Stroke is a brain injury caused by an interruption in blood flow to brain tissue due to a blocked or burst artery. It is also called a cerebral vascular accident (CVA) or brain attack.

Description

Arterial blood carries oxygen and nutrients to all cells of the body, including the brain. When arteries are unable to carry out this function due to constriction, obstruction, or rupture, the cells nourished by those arteries die. Thus, stroke can cause brain death or significant disability, including **paralysis**, speech difficulties, and mental and emotional problems. More than 2,400 years ago Hippocrates described stroke as the sudden onset of paralysis.

Types of stroke

Ischemic stroke—accounting for about 80% of all strokes—occurs when blood supply is cut off to a portion of the brain. Ischemic stroke caused by a blocked artery can cause the death of 2 million brain cells every minute. There are two types of ischemic stroke—thrombotic or cerebral thrombosis and embolic or cerebral **embolism**.

Cerebral thrombosis accounts for 40–50% of all strokes. As people age, atherosclerosis or hardening of the arteries occurs through the buildup of waxy, cholesterol-laden plaque that eventually narrows the interior of the arteries. This process can occlude or shut off the blood supply. Transient ischemic attacks (TIAs), or mini-strokes, are caused by the blockage of a very small artery or arteriole or the intermittent or temporary obstruction of a larger artery. TIAs usually last only minutes and affect only small areas of brain tissue, generally without noticeable permanent effects. However, TIAs are a warning signal for a possible future thrombotic stroke.

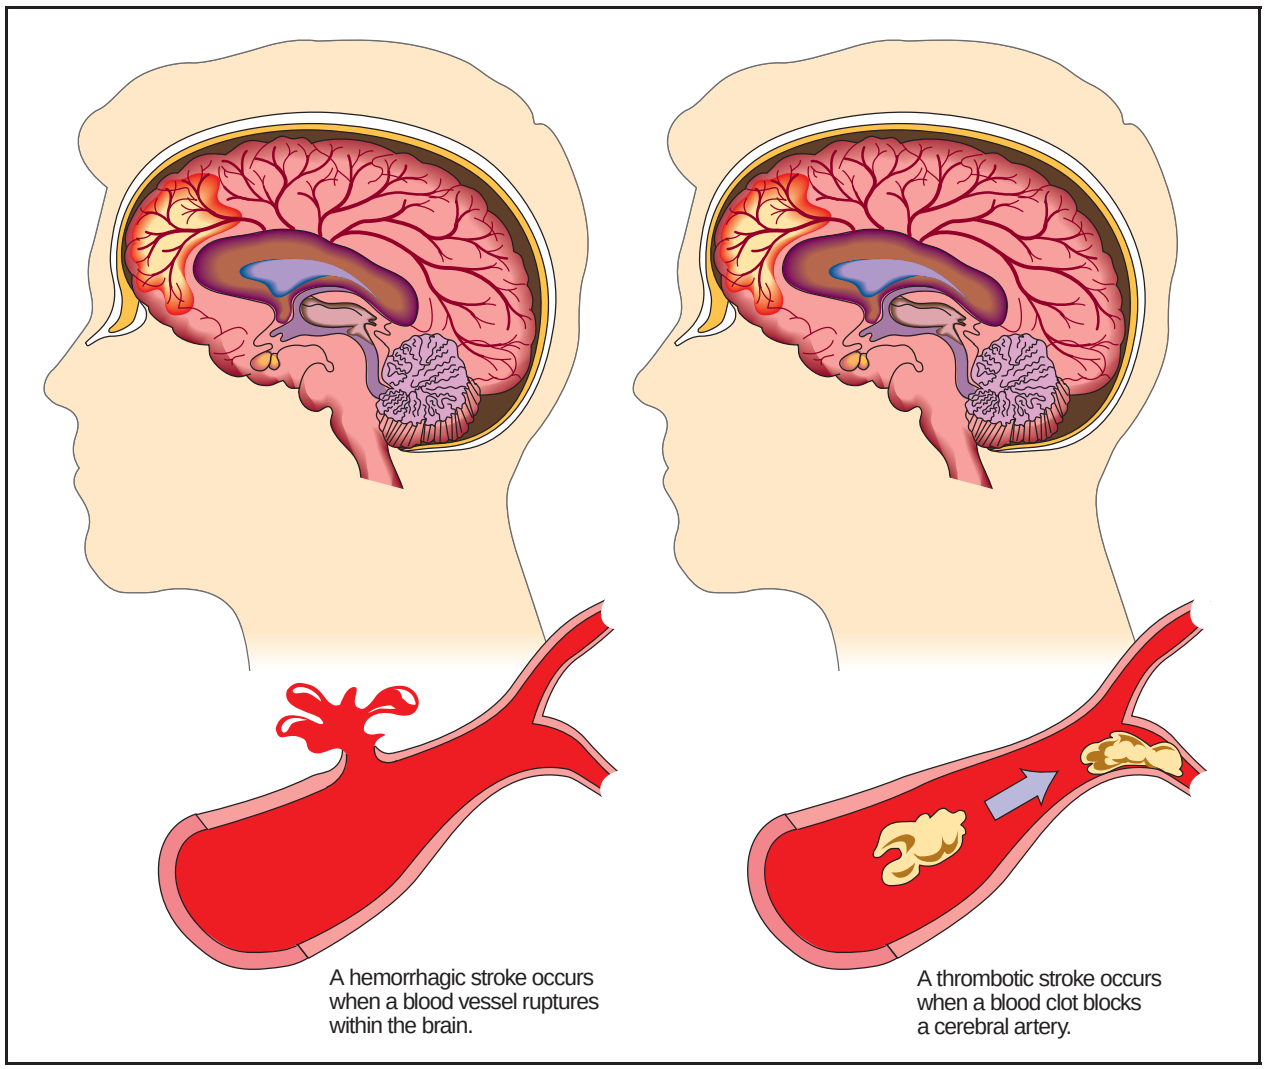
Cerebral embolism accounts for 25–30% of all strokes. An embolic stroke occurs when a blood clot moves through the circulatory system to block an artery, usually in the brain but occasionally an artery in the neck, especially the carotid artery.

Approximately 20% of strokes are hemorrhagic. Hemorrhagic strokes occur when a thin, weak spot in an artery in the brain balloons outward, producing an aneurysm that can burst, causing bleeding (hemorrhaging) in the brain.

Risk factors

The biggest risk factor for thrombotic stroke is age, since the incidence of atherosclerosis and high blood pressure increase with age. Strokes also appear to run in families. This may be because of an inherited susceptibility toward high blood pressure and diabetes—two of the major risk factors for stroke—or because of lifestyle risk factors within families. More than 9% of adult Americans have diabetes, and a 2012 study found that adults with diabetes were two to three times more likely to suffer ischemic stroke. Higher rates of high blood pressure, diabetes, and **smoking** among African Americans may account for their higher stroke risk. **Sickle cell disease**, an inherited disorder that affects African Americans, is also a risk factor for stroke. Other stroke risk factors are:

- diets high in cholesterol or fatty foods
- smoking, which doubles the risk of ischemic stroke



A hemorrhagic stroke (left) compared to a thrombotic stroke (right). *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

- obesity
- heart disease
- TIAs or previous stroke
- oral contraceptives or hormone replacement therapy
- polycythemia—excess red blood cells
- sleep apnea

The risk factors for hemorrhagic stroke are conditions that can weaken arteries supplying blood to the brain. These include high blood pressure, which can cause aneurysms, and hereditary malformations. Abuse of substances such as cocaine or amphetamines and chronic **alcoholism** can also weaken blood vessels and result in hemorrhagic stroke.

Risk factors for stroke in children include the following:

- congenital malformations of blood vessels or other structures in the brain
- brain infections such as encephalitis or meningitis
- head trauma
- blood disorders, especially sickle cell disease

Demographics

Stroke is the second most common cause of death worldwide and the most common cause of early disability. In the United States, stroke is the third leading cause of death and the leading cause of neurological disability, with 800,000 new stroke patients annually

WWW.BOOKBAZ.IR

and 3 million Americans permanently disabled from stroke. It can strike anyone at any age, including fetuses in the womb. However, the risk of stroke doubles with each decade over age 55, and two-thirds of all strokes occur in people over 65, who are also seven times more likely to die from stroke. Men are at higher risk for stroke than women, but more women die from stroke, probably because they tend to have strokes at an older age. Strokes in children are rare: about six cases per 100,000 children per year in North America. About one-third of these strokes are in newborns.

African Americans have almost double the incidence of stroke as white Americans, and twice as many die from stroke. Although Asian Americans have rates of stroke and stroke mortality similar to white Americans, Asians in the Far East have significantly higher rates.

A so-called stroke belt in the southeastern United States has been recognized for decades, and its high rate of stroke mortality cannot be accounted for solely by the higher percentage of African Americans or lower overall socioeconomic status. In particular, North Carolina, South Carolina, and Georgia have up to twice the stroke mortality rates as the country does as a whole.

Causes and symptoms

Causes

A thrombotic stroke is caused by a blood clot or thrombus—often resulting from atherosclerosis—blocking blood flow in the brain. Cerebral thrombosis occurs most often at night or early in the morning and is often preceded by a TIA.

An embolic stroke occurs when a blood clot from elsewhere in the circulatory system breaks free and becomes lodged in an artery supplying the brain. The most common cause of cerebral embolism is **atrial fibrillation**, in which the upper chambers (atria) of the heart beat weakly and rapidly so that they do not empty completely. This stagnant blood may form clots that can break off and enter the circulation. Atrial fibrillation is a factor in about 15% of all strokes.

Hemorrhagic stroke can be caused by the sudden bursting of a brain aneurysm, most often from high blood pressure. Brain aneurysms are surprisingly common—affecting about 6% of all Americans according to **autopsy** studies—yet they rarely cause symptoms unless they burst. Hemorrhagic stroke can also occur if thin, brittle arteries break and leak blood directly into the brain (intracerebral hemorrhage) or into the membranes covering the brain (**subarachnoid hemorrhage**). Intracerebral hemorrhages represent about 10% of all strokes, whereas subarachnoid hemorrhages account for about 7%. In addition to depriving affected brain tissue of its blood supply, the accumulation of fluid within the skull causes excessive pressure that can quickly lead to death.

Although the underlying causes of stroke are known, the immediate trigger is not usually apparent. It can be as simple as an abrupt change in body position, a loud noise, or an unexpected event.

Symptoms

Stroke symptoms depend on the part of the brain deprived of oxygen and how large an area is affected. The left and right hemispheres of the brain control movement on the opposite sides of the body. The left hemisphere is responsible for motor control and sensory discrimination on the right side of the body, and the right hemisphere is responsible for left body movements and sensations. Thus, a stroke on one side of the brain may affect movement and/or sensation on the opposite side of the body. Since communication and speech centers are predominately located in the left hemisphere, interruption of blood supply to that area can affect the ability to speak. Right brain strokes may affect spatial perception. Right-brain stroke patients also may deny their illness, neglect the affected side of their body, and behave impulsively.

Although strokes usually occur suddenly, symptoms of thrombotic stroke are more gradual and less dramatic due to the more gradual process of occlusion. Symptoms of embolic stroke have a rapid onset, and seizures or unconsciousness may be the first sign. Other symptoms may appear in minutes, hours, or—rarely—not for several days. Major stroke symptoms include headache—in the case of hemorrhagic stroke, often described as the worst **headache** ever—mental confusion, vertigo, vision problems, slurring of words, or **aphasia** (inability to speak or comprehend speech). Hemiplegia—weakness or paralysis on one side of the body—is a frequent symptom that often occurs first in the face, with facial drooping or slackness of the facial muscles on the affected side and difficulty swallowing. Other symptoms include sudden numbness or weakness in the face, arm, or leg, especially on one side of the body, or loss of balance or coordination.

With the possible exception of TIAs, strokes are always life-threatening emergencies. Because new treatments can reduce damage if initiated immediately, every minute counts. Diagnosis and treatment should begin as soon as possible, preferably onsite or during transport to a hospital.

Diagnosis

Examination

The examination has several purposes: checking the patient's airways, breathing, and circulation; identifying any neurological deficits; identifying potential cause(s) of the stroke; and identifying any coexisting conditions. The patient or a companion provides a description of the event. This is followed by a short neurological examination. The patient will be asked to answer questions and perform physical and mental tasks. The physician may use the National Institutes of Health (NIH) standardized Stroke Scale (NIHSS) to gauge the level of consciousness, visual function, movement, sensations, and speech. Other scales include the Glasgow **Coma** Scale, the Hunt and Hess Scale, and the Modified Rankin Scale. The emergency department physician will note symptoms and obtain a medical history with special emphasis on risk factors for stroke. The time of onset of symptoms is critical. If the patient awoke with symptoms, then the time of onset is defined as when the patient was last observed without symptoms.

Tests

Various blood tests may be performed to detect conditions or disorders that increase the risk of stroke.

WWW.BOOKBAZ.IR

Procedures

Various diagnostic procedures may be performed.

- Computed tomography (CT) scans may be used first to determine the cause of the stroke and the extent of injury.
- Magnetic resonance imaging (MRI) can locate small or deep brain injuries.
- Blood flow imaging for detecting the location and size of any blockages may be performed with ultrasound or angiography (x rays of vessels after the injection of a contrast dye).
- An electroencephalogram (EEG) measures the brain's electrical activity.
- Echocardiography uses ultrasound to image the heart and help determine whether an embolus caused the stroke.

Treatment

Effective stroke treatments have become available in recent decades. Immediate treatment is aimed at preventing further damage to the brain and is dependent on determining the type of stroke. A severe stroke that results in unconsciousness or coma requires medical monitoring and support, including oxygen, possibly intubation to assure an adequate airway and facilitate breathing, and intravenous fluids and **nutrition**.

A clot obstructing an artery is sometimes removed by endovascular methods using catheters or by surgery. **Endarterectomy** is the surgical removal of fatty deposits caused by atherosclerosis from a main artery to the brain. A mesh tube called a stent may be implanted inside the artery to prevent recurrent narrowing.

Emergency treatment of hemorrhagic stroke is aimed at controlling bleeding and intracranial pressure. Medications such as **aspirin** or warfarin that increase bleeding must be discontinued immediately, and transfusions of clotting factors may be necessary. Pressure on the brain must be relieved as quickly as possible to prevent further damage. Surgery may be required to stop bleeding and/or relieve pressure. Aneurysm clipping—clamping off the weak spot in the artery to prevent it from bursting—can prevent a second hemorrhagic stroke. Endovascular treatment uses a catheter to discharge tiny wire coils into the aneurysm to plug it.

Paralysis requires prevention of **contractures** (tightening of paralyzed limbs). This is accomplished through physiotherapy and may include the use of supportive braces for arms or hands and footboards. A severely ill stroke patient must be repositioned frequently to prevent complications such as **pneumonia** and venous or **pulmonary embolism**.

Drugs

Thrombolytics are drugs used to stop an ongoing ischemic stroke by dissolving the clot that is blocking blood flow to the brain. If administered intravenously within four and a half hours of symptom onset, tPA (tissue plasminogen activator), a genetically engineered form of the body's natural clot-buster, can be especially effective for improving recovery and decreasing long-term disability. However, tPA and other thrombolytics increase bleeding and carry a risk of cerebral hemorrhage and are only used for ischemic strokes.

Antithrombotics are used to treat ischemic strokes and to prevent future **blood clots**, since about 3% of stroke victims have a second stroke within 30 days, and one-third of recurrent strokes occur within two years. Heparin, warfarin (Coumadin), and enoxaparin are the most commonly prescribed blood thinners or anticoagulants. **Antiplatelet drugs** decrease the activity of platelets involved in the clotting process. Aspirin is the most commonly used antiplatelet drug. Others include clopidogrel, ticlopidine, and dipyridamole.

A diuretic or steroid medication may be used to relieve brain swelling from hemorrhagic stroke.

Rehabilitation

Rehabilitation from stroke is a comprehensive program for regaining as much function as possible and compensating for permanent losses. Rehabilitation is coordinated by a team of medical professionals and may be provided in an acute-care or rehabilitation hospital, long-term care facility, outpatient clinic, or at home.

Physical therapy is used to maintain and restore range of motion and strength in affected limbs and to maximize mobility, including the use of aids such as wheelchairs, braces, and canes. Muscle spasticity and contractures are common during stroke recovery. Contractures may be treated with a combination of stretching and splinting. Weakness and loss of coordination of the swallowing muscles may be treated with retraining exercises and temporary use of pureed foods. A speech-language pathologist may work on swallowing skills as well as on communication. **Occupational therapy** addresses self-care skills, such as feeding, bathing, and dressing, and helps the patient develop effective compensatory strategies and devices

for activities of daily living. Rehabilitation may be complicated by cognitive losses, including diminished ability to understand and follow directions, as well as by depression, which affects 30–60% of stroke patients and may require antidepressants and/or **psychotherapy**.

A social worker may help coordinate services and ease the transition from hospital to home. However, caring for a stroke patient requires learning a new set of skills and adapting to new demands and limitations. Home caregivers may develop **stress**, **anxiety**, and depression. Caring for the caregiver is an important part of overall stroke rehabilitation. Support groups can be an important source of information, advice, and comfort.

Prognosis

Stroke survival improved significantly between 1990 and 2014, due to advances in emergency treatment, decreased smoking, and better control of high blood pressure and **cholesterol** levels. Approximately 25% of stroke patients recover completely, about 5% are permanently disabled and require long-term care, and about 20% of all strokes are fatal. About half of all stroke patients require rehabilitative and restorative therapies. Prognosis depends on the patient's age, the type and location of the stroke, and time elapsed between symptom onset and initiation of treatment. Emergency treatment and comprehensive rehabilitation can significantly improve both survival and recovery. However, recurrent stroke is common: about 25% of patients who recover from a first stroke will have another within five years. The risk of severe disability or death increases with each stroke, although the risk of recurrent stroke decreases with time.

Deep venous thrombosis (DVT), in which a clot forms within an immobilized limb, is one of the most common complications following stroke. Clots that break free often become lodged in an artery feeding the lungs, causing a pulmonary embolism—a common cause of death in the weeks following a stroke. Resuming activity within a day or two after the stroke, using pressure stockings, and taking anticoagulants are important preventive measures.

Stroke in children can be devastating. Between 20% and 35% of newborns who survive a stroke have a second stroke. More than 66% of older children who suffer strokes have cognitive deficits, seizures, behavioral problems, personality changes, and/or physical disabilities. However, the plasticity of children's immature brains may enable them to adapt to and compensate for deficits and injury better than adult stroke victims.

Prevention

Strokes are preventable to a significant extent. Numerous studies have demonstrated that one baby aspirin per day is an excellent blood-thinning and clot-reducing measure. In addition to antiplatelet and anticoagulant therapies, blood pressure control is the single most important factor for preventing stroke. Blood pressure should be checked regularly, and consistently elevated blood pressure (systolic above 140–150 and diastolic above 90–100) should be treated. Cholesterol-lowering medications may also help prevent stroke. Treatment for atrial fibrillation significantly reduces the risk of stroke. Preventive anticoagulant therapy may benefit those with untreated atrial fibrillation.

Cigarette smoking almost doubles the risk of ischemic stroke and is associated with other risk factors for stroke. Avoiding alcohol, drugs, and secondhand smoke is also important.

Diet, including lowering **sodium** (salt) intake, **exercise**, and weight control are important for lowering blood pressure and reducing the risk of stroke. Studies have demonstrated that **diets** high in fruits and vegetables (particularly leafy green vegetables and cruciferous vegetables such as broccoli, cauliflower, and cabbage) can reduce the risk of ischemic stroke. Replacing meat and trans fats with fruits and vegetables further reduces stroke risk. Two analyses published in 2013 indicated that consumption of dietary fiber is inversely related to the risk of stroke, independently of other risk factors.

Stroke damage may be significantly reduced by emergency treatment; thus, knowing the symptoms of stroke and seeking immediate treatment is of the utmost importance. Furthermore, people should see their doctors immediately if they experience a TIA.

Stuttering

Definition

There is no standard definition of stuttering (sometimes called stammering) but most attempt to define stuttering as blockages, discoordination, or fragmentations of the forward flow of speech (fluency). These

stoppages, referred to as disfluencies, are often excessive and characterized by specific types of disfluency. These types of disfluencies include repetitions of sounds and syllables, prolongation of sounds, and blockages of airflow. Individuals who stutter are often aware of their stuttering and feel a loss of control when they are disfluent. Both children and adult stutterers expend an excessive amount of physical and mental energy when speaking. Older children and adults who stutter show myriad negative reactive behaviors, feelings, and attitudes. These behaviors, referred to as secondary behaviors, make the disorder more severe and difficult.

Demographics

Stuttering is a relatively low-prevalence disorder. According to the Stuttering Foundation of America, about 3 million people in the United States stutter as of 2015. Worldwide, 70 million or roughly 1% of people currently have a stuttering disorder. This figure differs from incidence, or number of individuals who have been diagnosed with stuttering at some point in their lives. Research suggests that roughly 5% of the population have been diagnosed with a stuttering disorder at some point across the life span. This difference suggests that a significant number of individuals who stutter develop through or outgrow the problem.

Stuttering is most common in children between the ages of two and five, the period when they are learning to speak. The majority of these children will eventually stop stuttering. In adults, approximately three times as many men stutter as women. The sex ratio seems to be lower in early childhood, with a similar number of girls and boys stuttering. The ratio of boys to girls appears to get larger as children become older. This phenomenon suggests that males are more likely to continue to stutter than females.

Description

Stuttering is a confusing and often misunderstood developmental speech and language disorder. Before discussing stuttering, it is important to understand the concepts of speech fluency and disfluency. Fluency is generally described as the forward flow of speech. For most speakers, fluent speech is easy and effortless. Fluent speech is free of any interruptions, blockages, or fragmentations. Disfluency is defined as a breakdown or blockage in the forward flow of speech, or fluency. For all speakers, some occurrence of disfluency is normal. For example, people may insert short sounds or words, referred to as interjections or fillers when speaking; examples of such are "um," "like," or "uh." Also, speakers might repeat phrases, revise words or phrases, or sometimes repeat whole words for the purpose of clarification. For young children, disfluency is a part of the normal development of speech and language, especially during the preschool years (between the ages of two and five years).

The occurrence of disfluency is not the same as stuttering, though stuttered speech is characterized by an excessive amount of disfluency. The disfluencies produced by people who stutter will often be similar to those in the speech of individuals who do not stutter; however, certain types of disfluent behavior are likely to appear only in the speech of people who stutter. These disfluencies are sound and syllable repetitions (i.e. ca- ca-ca-cat), sound prolongations ("sssss–salad," "ffffff-fish"), and complete blockages of airflow. These behaviors, often referred to as stuttering type disfluencies, distinguish stuttered speech from nonstuttered speech.

Unlike speakers who do not stutter, most people who stutter react negatively to their disfluencies. A person may develop a number of physical reactions, including tension of the muscles involved in speech (tongue, jaw, lips, or chest, for example) and tension in muscles not related to speech (such as shoulders, limbs, and forehead). In addition to these physiological reactions, people who stutter often have negative emotional reactions to the disorder. Among the emotions that people who stutter report are embarrassment, guilt, and frustration.

Finally, many people who stutter develop a number of negative attitudes and beliefs regarding themselves and speaking—because of their stuttering. These may be negative attitudes and beliefs in certain speaking situations, with people with whom they interact, and in their own abilities. These physiological, emotional, and attitudinal (cognitive) reactions to stuttering, described as secondary stuttering behaviors, are often very disruptive to the communication process and the person's life.

Stuttering behaviors can develop and vary throughout the life span. Sometimes, children will experience periods when stuttering appears to go away for a time, only to return in a more severe pattern. Many children, (estimates range between 50 and 80%) will develop normal fluency after periods of stuttering. For those who continue to stutter during late childhood, adolescence, and into adulthood, stuttering can become a chronic problem. Lifelong efforts will be needed to cope successfully with the behavior.

WWW.BOOKBAZ.IR

Due to the effect that stuttering has on communication, the person who stutters may experience certain difficulties in various parts of his or her life. These problems might be secondary to factors inside the person (symptoms of stuttering) and outside the person (society's attitudes toward stuttering and other barriers). For example, many people who stutter report difficulties in social settings. Children who stutter often experience teasing and other social penalties. Adolescents and adults also report a variety of social problems. Academic settings may be difficult for children who stutter because of the emphasis most schools place on verbal performance in the classroom.

There is some evidence that people who stutter confront barriers in employment, at least for jobs that require interacting with the public. These barriers may take the form of inability to do certain tasks easily (talking on the phone, for example), limitations in job choices, and discrimination in the hiring and promotion processes.

Risk factors

According to the Stuttering Foundation of America (SFA), the following are known risk factors for stuttering:

- Family history of stuttering.
- Sex. Boys are at greater risk of stuttering than girls.
- Age when stuttering begins. Children who begin to stutter before age three are more likely to outgrow it than those who begin to stutter later.
- Time elapsed since onset of stuttering. Children who have been stuttering longer than six months are less likely to outgrow the condition.

As far as is known as of 2015, race, ethnicity, or native language are not risk factors for stuttering. The rate of stuttering and sex ratio are thought to be similar throughout the world, although some researchers think that rates of stuttering are higher in Africa than elsewhere. What does seem to vary most widely from country to country is cultural attitudes toward stuttering.

Causes and symptoms

Although research has not identified a single cause of stuttering as of 2015, there appear to be several factors that are viewed as being important to the onset and development of stuttering. Therefore, stuttering is often described as multifactorial and having possibly multiple causes. First, there is a genetic predisposition to stutter, as evidenced by studies of families and twins. In 2010, researchers at NIDCD identified three specific genes—one on chromosome 12 and two on chromosome 16—that are linked to stuttering. The genes are known as GNPTAB, GNPTG, and NAGPA.

A second important factor in stuttering the onset of stuttering is the physiological makeup of people who stutter. Research suggests that the brains of people who stutter may function abnormally during speech production. These differences in functioning may lead to breakdowns in speech production and to the development of disfluent speech.

Third, there is some evidence that speech and language development is an important issue in understanding the development of stuttering. Studies have found some evidence that children show stuttering type behaviors may also have other difficulties with speech-language. Additionally, children with speech-language delays often show stuttering-type behaviors. Finally, environmental issues have a significant impact on the development of stuttering behaviors. An environment that is overly stressful or demanding may cause children to have difficulties developing fluent speech. Although the environment, in particular parental behaviors, does not cause stuttering, it is an important factor that might adversely affect a child who is operating at a reduced capacity for developing fluent speech.

There is no evidence that stuttering is secondary to a psychological disturbance. It is reasonable to assume that stuttering might have some effect on psychological adjustment and a person's ability to cope with speaking situations. People who stutter might experience a lower self-esteem, and some might report feeling depressed. These feelings and difficulties with coping are most likely the result and not the cause of stuttering. In addition, several research studies have reported that many people who stutter report high levels of **anxiety** and **stress** when they are talking and stuttering. These feelings, psychological states, and difficulties with coping are most likely the result and not the cause of stuttering.

Generally, children begin to stutter between the ages of two and five years. This type of stuttering is categorized as developmental stuttering. Another major category of stuttering is called neurogenic. Neurogenic stuttering results from brain damage, such as a **stroke**, a traumatic injury to the brain, or a degenerative neurological disease. In other cases, stuttering may be secondary to a psychological conversion disorder due to a psychologically traumatic event. When stuttering has abrupt onset secondary to

a psychological **trauma**, it is described as psychogenic stuttering. As of 2015, psychogenic stuttering is considered the least common type.

As stated earlier, the primary symptoms of stuttering include excessive disfluency, both stuttering and normal types (core behaviors), as well as physical, emotional, and cognitive reactions to the problem. These behaviors vary in severity across people who stutter from very mild to very severe. Additionally, behaviors will vary considerably across different speaking situations. There are specific situations when people tend to experience more stuttering (such as talking on the phone or with an authority figure) or less stuttering (speaking with a pet or to themselves, for example). It is likely that this variability might even extend to people having periods (days and even weeks) when they can maintain normally fluent or nonstuttered speech.

Other symptoms that may be associated with stuttering in children include eye blinking, tremor in the lips or jaw, and tension or movement of the face or upper body.

Diagnosis

Examination

Speech-language pathologists (SLPs) are responsible for making the diagnosis and managing the treatment of adults and children who stutter. Preferably, a board-certified speech-language pathologist should be sought for direct intervention or consulting. Diagnosis of stuttering, or identifying children at risk for stuttering, is difficult because most children show excessive disfluencies in their speech. With children, diagnostic procedures include the collection and analysis of speech and disfluent behaviors in a variety of situations. In addition, the child's general speech-language abilities will be evaluated.

Finally, the speech-language pathologist will interview parents and teachers regarding the child's general developmental, speech-language development, and their perceptions of the child's stuttering behaviors. For adults and older children, diagnostic procedures will also include gathering and analyzing speech samples from a variety of settings. In addition, the speech-language pathologist will conduct a lengthy interview with the person about their stuttering and history of their stuttering problem. Finally, the person who stutters might be asked to report his or her attitudes and feelings related to stuttering, either while being interviewed or by completing a series of questionnaires.

Tests

In some cases, the child may be referred to an otolaryngologist (specialist in ear, nose, and throat disorders) or a neurologist to rule out the possibility that abnormalities in the structure of the child's tongue or mouth, or a brain disorder, are related to the stuttering.

Treatment

Traditional

GENERAL CONSIDERATIONS. Experts generally accept the view that conducting interventions with children and families early in childhood (preschool) is the most effective means of total recovery from stuttering. The chances for a person to recover fully from stuttering by obtaining near-normal fluency are reduced as the person ages. This is the reason that early intervention is critical. For older children and adults for which stuttering has become a chronic disorder, the focus of therapy is on developing positive coping mechanisms for dealing with the problem. This therapy varies in success based on the individual.

TREATMENT OPTIONS FOR YOUNG CHILDREN. Treatment of young children generally follows one of two basic approaches. These approaches may also be combined into a single treatment program. The first type of approach, often referred to as indirect therapy, focuses on altering the environment to allow the child opportunities to develop fluent speech. With this approach, counseling parents regarding the alteration of behaviors that affect fluency is the focus. For example, parents may be taught to reduce the amount of household stress on the level of speech-language demands being placed on the child. In addition,

WWW.BOOKBAZ.IR

parents may be advised to change characteristics of their speech, such as their speech rate and turn-taking style; this is done to help their children develop more fluent speech.

The other basic approach in treatment with young children targets the development of fluent speech. This type of approach, often referred to as direct therapy, teaches children to use skills that will help them improve fluency, and they are sometimes given verbal rewards for producing fluent speech.

TREATMENT OPTIONS FOR OLDER CHILDREN AND ADULTS. Treatment approaches for older children and adults usually take one of two forms. These approaches target either helping the person to modify his or her stuttering or fluency. Approaches that focus on modifying stuttering usually teach individuals to reduce the severity of their stuttering behaviors by identifying and eliminating all of the secondary or reactive behaviors. Individuals also work to reduce the amount of emotional reaction toward stuttering.

Finally, the speech-language pathologist will help the individual to learn techniques that allow them to stutter in an easier manner. Therapy does not focus on helping the individual to speak fluently, although most individuals will attain higher levels of fluency if this approach is successful. The other groups of approaches focus on assisting adults and children who stutter to speak more fluently. This type of therapy, which focuses less on changing secondary and emotional reactions, helps individuals to modify their speech movements in a specific manner that allows for fluent sounding speech. These procedures require the individual to focus on developing new speech patterns. This often requires a significant amount of practice and skill. The successful outcome of these approaches is nonstuttered, fluent sounding speech. Many therapists integrate stuttering modification and fluency shaping approaches into more complete treatment programs. In addition, psychological counseling may be used to supplement traditional **speech therapy**.

Drugs

There is no drug that has been approved by the Food and Drug Administration (FDA) just for the treatment of stuttering. Although various medications used to treat **epilepsy**, depression, and **anxiety disorders** have been tried as therapy for stuttering, all of these agents have problematic side effects, and none has been particularly successful in treating stuttering. There are, however, isolated case studies of successful treatment of neurogenic stuttering using **antipsychotic drugs**. As of 2015, NIDCD does not recommend the use of drugs to treat stuttering.

Another method of therapy for stuttering is the use of electronic devices to improve fluency. One type of device fits into the ear like a hearing aid and digitally replays the child's voice so that it sounds as if the child is speaking in unison with someone else. Another type of device, called delayed auditory feedback, forces children to speak more slowly so that their voice will not sound distorted through the machine. NIDCD researchers maintain that the evidence about the success of these devices is mixed as of 2015: "Questions remain about how long such effects may last and whether people are able to easily use these devices in real-world situations."

Prognosis

The prognosis for developmental stuttering is generally good. About 65% of preschool children who stutter outgrow the condition and 74% recover by their early teens. In general, girls have a better prognosis than boys.

According to the American Speech-Language-Hearing Association (ASHA), no single factor can be used to estimate a given child's prognosis for full recovery from stuttering. Complete recovery from severe stuttering is most likely when children and their families receive treatment close to the time of onset. Thus, early identification and treatment of stuttering is critical. For older children and adults, stuttering becomes a chronic problem that requires a lifetime of formal and self–directed therapy. For individuals who show this more chronic form of the disorder, internal motivation for change and support from significant others is going to be an important part of recovery.

Friends, an association for young people who stutter, was founded in 1997 by John Ahlbach, an adult who stutters, and Lee Caggiano, a speech-language therapist who specializes in stuttering and is the mother of a son who stutters. Friends offers online support to young people who stutter, their parents, and speech-language professionals who work with them. The group also publishes books and a bimonthly newsletter as well as holding an annual convention.

Prevention

With the exception of the small number of cases in which stuttering is caused by a **traumatic brain injury**, the condition is not preventable as of 2015.

Subacute sclerosing panencephalitis

Definition

Subacute sclerosing panencephalitis is a rare, progressive brain disorder caused by an abnormal immune response to the **measles** virus.

Description

This fatal condition is a complication of measles, and affects children and young adults before the age of 20. It usually occurs in boys more often than in girls but is extremely rare, appearing in only one out of a million cases of measles.

Causes and symptoms

Experts believe this condition is a form of measles encephalitis (swelling of the brain), caused by an improper response by the immune system to the measles virus.

The condition begins with behavioral changes, **memory loss**, irritability, and problems with school

WWW.BOOKBAZ.IR

KEY TERMS

work. As the neurological damage increases, the child experiences seizures, involuntary movements, and further neurological deterioration. Eventually, the child starts suffering from progressive **dementia**. The optic nerve begins to shrink and weaken (atrophy) and subsequently the child becomes blind.

Diagnosis

Blood tests and spinal fluid reveal high levels of antibodies to measles virus, and there is a characteristically abnormal electroencephalogram (EEG), or brain wave test. Typically, there is a history of measles infection two to ten years before symptoms begin.

Treatment

There is no standard treatment and a number of **antiviral drugs** have been tested with little success. Treatment of symptoms, including the use of **anticonvulsant drugs**, can be helpful.

Prognosis

While there may be periodic remissions during the course of this disease, it is usually fatal (often from **pneumonia**) within one to three years after onset.

Subarachnoid hemorrhage

Definition

A subarachnoid hemorrhage is an abnormal and very dangerous condition in which blood collects beneath the arachnoid mater, a membrane that covers the brain. This area, called the subarachnoid space, normally contains cerebrospinal fluid. The accumulation of blood in the subarachnoid space can lead to **stroke**, seizures, and other complications. Additionally, subarachnoid hemorrhages may cause permanent brain damage and a number of harmful biochemical events in the brain. A subarachnoid hemorrhage and the related problems are frequently fatal.

Description

Subarachnoid hemorrhages are classified into two general categories: traumatic and spontaneous. Traumatic refers to brain injury that might be sustained in an accident or a fall. Spontaneous subarachnoid hemorrhages occur with little or no warning and are frequently caused by ruptured aneurysms or blood vessel abnormalities in the brain.

Traumatic brain injury is a critical problem in the United States. According to annual figures compiled by the Brain Injury Association, approximately 373,000 people are hospitalized, more than 56,000 people die, and 99,000 survive with permanent disabilities due to traumatic brain injuries. The leading causes of injury are bicycle, motorcycle, and automobile accidents, with a significant minority due to accidental falls, and sports and recreation mishaps.

Exact statistics are not available on traumatic subarachnoid hemorrhages, but several large clinical studies have found an incidence of 23–39% in relation to severe **head injury**. Furthermore, subarachnoid hemorrhages have been described in the medical literature as the most common brain injury found during **autopsy** investigations of head **trauma**.

Spontaneous subarachnoid hemorrhages are often due to an aneurysm (a bulge or sac-like projection from a blood vessel) which bursts. **Arteriovenous malformations** (AVMs), which are abnormal interfaces between arteries and veins, may also rupture and release blood into the subarachnoid space. Both aneurysms and AVMs are associated with weak spots in the walls of blood vessels and account for approximately 60% of all spontaneous subarachnoid hemorrhages. The rest may be attributed to other causes, such as cancer or infection, or are of unknown origin.

In industrialized countries, it is estimated that there are 6.5–26.4 cases of spontaneous subarachnoid hemorrhage per 100,000 people annually. Certain factors raise the risk of suffering a hemorrhage. Aneurysms are acquired over a person's lifetime and are rarely a factor in subarachnoid hemorrhage before age 20. Conversely, AVMs are present at birth. In some cases, there may be a genetic predisposition for aneurysms or AVMs. Other factors that have been implicated, but not definitively linked to spontaneous subarachnoid hemorrhages, include atherosclerosis, cigarette use, extreme alcohol consumption, and the use of illegal drugs, such as cocaine. The exact role of high blood pressure is somewhat unclear, but since it does seem linked to the formation of aneurysms, it may be considered an indirect risk factor.

The immediate danger due to subarachnoid hemorrhage, whether traumatic or spontaneous, is ischemia. Ischemia refers to tissue damage caused by restricted or blocked blood flow. The areas of the brain that do not receive adequate blood and oxygen can suffer irreparable injury, leading to permanent brain damage or death. An individual who survives the initial hemorrhage is susceptible to a number of complications in the following hours, days, and weeks.

The most common complications are intracranial **hypertension**, vasospasm, and **hydrocephalus**. Intracranial hypertension, or high pressure within the brain, can lead to further bleeding from damaged blood vessels; a complication associated with a 70% fatality rate. Vasospasm, or blood vessel constriction, is a principal cause of secondary ischemia. The blood vessels in the brain constrict in reaction to chemicals released by blood breaking down within the subarachnoid space. As the blood vessels become narrower, blood flow in the brain becomes increasingly restricted. Approximately one third of spontaneous subarachnoid hemorrhages and 30–60% of traumatic bleeds are followed by vasospasm. Hydrocephalus, an accumulation of fluid in the chambers of the brain (ventricles) due to restricted circulation of cerebrospinal fluid, follows approximately 15% of subarachnoid hemorrhages. Because cerebrospinal fluid cannot drain properly, pressure accumulates on the brain, possibly prompting further ischemic complications.

Causes and symptoms

Whether through trauma or disease, subarachnoid hemorrhages are caused by blood being released by a damaged blood vessel and accumulating in the subarachnoid space. Symptoms associated with traumatic subarachnoid hemorrhage may or may not resemble those associated with spontaneous hemorrhage, as trauma can involve multiple injuries with overlapping symptoms.

Typically, a spontaneous subarachnoid hemorrhage is indicated by a sudden, severe **headache**. Nausea, **vomiting**, and **dizziness** frequently accompany the **pain**. Loss of consciousness occurs in about half the cases of spontaneous hemorrhage. A **coma**, usually brief, may occur. A stiff neck, **fever**, and aversion to light may appear following the hemorrhage. Neurologic symptoms may include partial **paralysis**, loss of vision, seizures, and speech difficulties.

Spontaneous subarachnoid hemorrhages may be preceded by warning signs prior to the initial bleed. Sentinel, or warning, headaches may be present in the days or weeks before an aneurysm or AVM ruptures. These headaches can be accompanied by dizziness, nausea, and vomiting, and possibly neurologic symptoms. Approximately 50% of AVMs are discovered before they bleed significantly; however, most aneurysms are not diagnosed before they rupture.

Diagnosis

To make a diagnosis, a healthcare provider takes a detailed history of the symptoms and does a **physical examination**. The symptoms may mimic other disorders and diagnosis can be complicated, especially if the individual is unconscious. The sudden, severe headache can fuel suspicion of a subarachnoid hemorrhage or similar event, and a computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI) scan is considered essential to a quick diagnosis. The MRI is less sensitive than the CT in detecting acute subarachnoid bleeding, but more sensitive in diagnosing AVM or aneurysm.

A CT scan reveals blood that has escaped into the subarachnoid space. For the best results, the scan should be done within 12 hours of the hemorrhage. If this is not possible, **lumbar puncture** and examination of the cerebrospinal fluid is advised. Lumbar puncture is also done in cases in which the CT scan doesn't reveal a hemorrhage, but there is a high suspicion that one has occurred. In subarachnoid hemorrhage, cerebrospinal fluid shows red blood cells and/or xanthochromia, a yellowish tinge caused by blood breakdown products. Xanthochromia first appears six to 12 hours after subarachnoid hemorrhage, making it advisable to delay lumbar puncture until at least 12 hours after the onset of symptoms for a more definite diagnosis.

KEY TERMS

Aneurysm—A weak point in a blood vessel where the pressure of the blood causes the vessel wall to bulge outwards. An aneurysm may also appear as a sac-like projection from the blood vessel wall.

Arachnoid mater—One of three membranes that encase the brain and spinal cord. The arachnoid mater is the middle membrane.

Arteriovenous malformation—An abnormal tangle of arteries and veins in which the arteries feed directly into the veins without a normal intervening capillary bed.

Atherosclerosis—An abnormal condition in which lipids, or fats, form deposits on the inside walls of blood vessels.

Cerebral angiography—A medical test in which an x-ray visible dye is injected into blood vessels to allow them to be imaged on an x ray.

Cerebrospinal fluid—The clear, normally colorless fluid found within the subarachnoid space.

Computerized tomography (CT) scan—Cross-sectional x rays of the body compiled to create a three-dimensional image of the body's internal structures.

Hemorrhage—The escape of blood from blood vessels.

Hydrocephalus—Englargement of the chambers in the brain (ventricles) caused by an accumulation of cerebrospinal fluid.

Intracranial hypertension—Abnormally high pressure within the brain.

Ischemia—A condition in which blood flow is cut off or restricted from a particular area. The tissue becomes starved of oxygen and nutrients, resulting in tissue death.

Ischemic—Referring to ischemia.

Lumbar puncture—A diagnostic procedure in which a needle is inserted into the lower spine to withdraw a small amount of cerebrospinal fluid. This fluid is examined to assess trauma to the brain.

Subarachnoid—Referring to the space underneath the arachnoid mater.

Vasospasm—The constriction or narrowing of blood vessels. In cases of hemorrhage, the constriction is prompted by chemical signals from the escaped blood as it breaks down.

Once a hemorrhage, AVM, or aneurysm has been diagnosed, further tests are done to pinpoint the damage. The CT scan may be useful in giving the general location, but cerebral **angiography** maps out the exact details. This procedure involves injecting a special dye into the blood stream. This dye makes blood vessels visible in x rays of the area.

Treatment

The initial course of treatment focuses on stabilizing the hemorrhage victim. Depending on the individual's condition, this may involve intubation and mechanical ventilation, supplemental oxygen, intravenous fluids, and close monitoring of vital signs. If the person suffers seizures, an anticonvulsant, such as phenytoin (Dilantin), is administered. Nimodipine, a **calcium** channel blocker, may be given to prevent vasospasm and its complications. Sedatives and medications for pain, nausea, and vomiting are administered as needed. Once the individual is stabilized, cerebral angiography is done to locate the damaged blood vessel. This information and the individual's condition are considered before attempting surgical treatment. Surgery is necessary to remove the damaged area of the blood vessel and prevent a second hemorrhage. The specific neurosurgical procedures depend on the location and type of blood vessel damage. Typically, clip ligation is the preferred means of treating an aneurysm, and surgical excision, radiosurgery, or endovascular embolization are used to manage an AVM.

Prognosis

Individuals who are conscious and demonstrate few neurologic symptoms when they reach medical help have the best prognosis. However, the overall prospects for subarachnoid hemorrhage patients are generally not good. Of the individuals who suffer an aneurysmal hemorrhage, approximately 15% do not live long enough to get medical treatment. Another 20–40% will not survive the complications caused by the hemorrhage, and approximately 12% of the survivors will experience permanent neurologic disability. Neurologic disabilities may include partial paralysis, weakened or numbed areas of the body, cognitive or speech difficulties, and vision problems. Individuals whose subarachnoid hemorrhages occur as a result of AVMs have a slightly better prognosis, although the risk of death is approximately 10–15% for each hemorrhage.

Subarachnoid hemorrhage associated with traumatic brain injury has a poor prognosis. In clinical studies, 46–78% of head injury cases involving subarachnoid hemorrhage resulted in severe disability, vegetative survival, or death. Furthermore, it is possible that traumatic subarachnoid hemorrhages are accompanied by additional injuries, which would further diminish survival and recovery rates.

Prevention

Traumatic brain injury is the leading cause of subarachnoid hemorrhages, so it follows that efforts to prevent head injury would prevent these hemorrhages. Since accidents cannot always be prevented, measures to minimize potential damage are always advisable. Use of activity-appropriate protective gear, such as bicycle helmets, motorcycle helmets, and sports head gear, is strongly encouraged and promoted by medical associations, consumer organizations, advocacy groups, and healthcare professionals. These same groups also advise using seat belts in automobiles.

Spontaneous subarachnoid hemorrhages are more difficult to prevent. Since there may be a genetic component to aneurysms and AVMs, close relatives to individuals with these conditions may consider being screened to assess their own status. Quitting **smoking** and keeping blood pressure within normal limits may also reduce the risk of suffering a spontaneous subarachnoid hemorrhage.

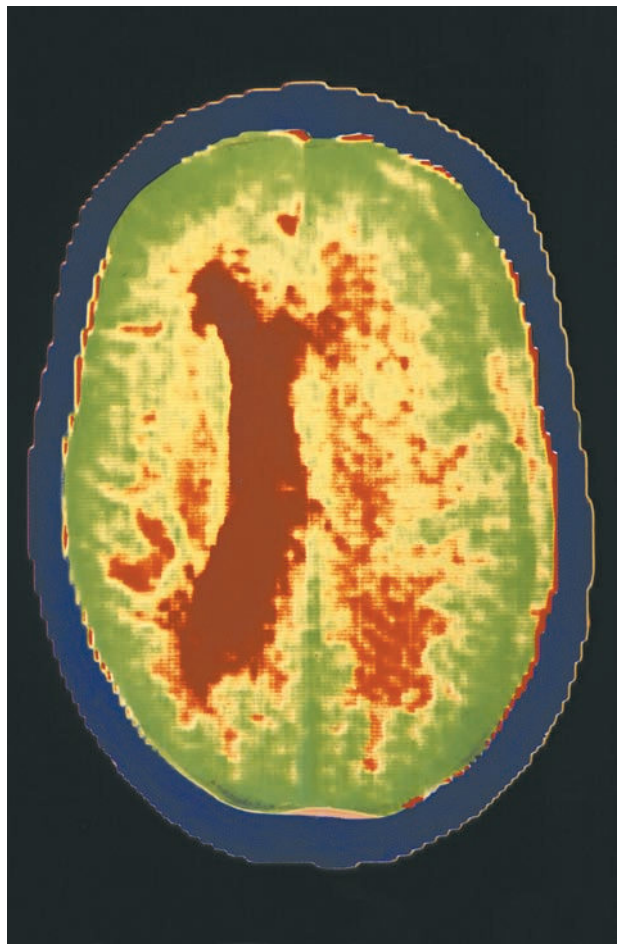
Subdural hematoma

Definition

A subdural hematoma is a collection of blood in the space between the outer layer (dura) and middle layers of the covering of the brain (the meninges). It is most often caused by torn, bleeding veins on the inside of the dura as a result of a blow to the head.



CT scan indicating subdural hematoma highlighted as a red mass on the center left of the brain. *(Photo Researchers, Inc.)*

Description

Subdural hematomas most often affect people who are prone to falling. Only a slight hit on the head or even a fall to the ground without hitting the head may be enough to tear veins in the brain, often without fracturing the skull. There may be no external evidence of the bruising on the brain's surface.

Small subdural hematomas may not be very serious, and the blood can be slowly absorbed over several weeks. Larger hematomas, however, can gradually enlarge over several weeks, even though the bleeding has stopped. This enlargement can compress the brain itself, possibly leading to death if the blood is not drained.

The time between the injury and the appearance of symptoms can vary from less than 48 hours to several weeks, or more. Symptoms appearing in less than 48 hours are due to an acute subdural hematoma. This type of bleeding is often fatal, and results from tearing of the venous sinus. If more than two weeks have passed before symptoms appear, the condition is called a chronic subdural hematoma, resulting from tearing of the smaller vein. The young and the old are most likely to experience a chronic condition. This chronic form is less risky, as pressure of the veins against the skull lessens the bleeding. Prompt medical care can reduce the probability of permanent brain damage.

Causes and symptoms

A subdural hematoma is caused by an injury to the head that tears blood vessels. In childhood, hematomas are a common complication of falls. A subdural hematoma also may be an indication of **child abuse**, as evidenced by **shaken baby syndrome**.

Symptoms tend to fluctuate, and include:

- headache
- episodes of confusion and drowsiness
- one-sided weakness or paralysis
- lethargy
- enlarged or asymmetric pupils
- convulsions or loss of consciousness after head injury
- coma

A doctor should be contacted immediately if symptoms appear. Because these symptoms mimic the signs of a **stroke**, the patient should tell the doctor about any **head injury** within the previous few months.

In an infant, symptoms may include increased pressure within the skull, growing head size, bulging fontanelle (one of two soft spots on a infant's skull), **vomiting**, irritability, lethargy, and seizures. In cases of child **abuse**, there may be **fractures** of the skull or other bones.

Diagnosis

A chronic subdural hematoma can be difficult to diagnose but a slow loss of consciousness after a head injury is assumed to be a hematoma unless proven otherwise. The hematoma can be confirmed with **magnetic resonance imaging** (MRI), which is the preferred type of scan; a hematoma can be hard to detect on a computed tomography scan (CT scan), depending on how long after the hemorrhage the CT is done.

Treatment

Small hematomas that do not cause symptoms may not need to be treated. Otherwise, the hematoma should be surgically removed. Liquid blood can be drained from burr holes drilled into the skull. The surgeon may have to open a section of skull to remove a large hematoma or to tie off the bleeding vein.

Corticosteroids and **diuretics** can control brain swelling. After surgery, **anticonvulsant drugs** (such as phenytoin) may help control or prevent seizures, which can begin as late as two years after the head injury.

Prognosis

If treatment is provided soon enough, recovery is usually complete. **Headache**, **amnesia**, attention problems, **anxiety**, and giddiness may continue for some time after surgery. Most symptoms in adults usually disappear within six months, with further improvement over several years. Children tend to recover much faster.

Prevention

Because a subdural hematoma usually follows a head injury, preventing head injury can prevent a hematoma.

Substance abuse and dependence

Definition

Substance abuse and dependence refer to any continued pathological use of a medication, non-medically indicated drug (called drugs of abuse), or toxin. They normally are distinguished as follows.

Substance abuse is any pattern of substance use that results in repeated adverse social consequences related to drug-taking—for example, interpersonal conflicts, failure to meet work, family, or school obligations, or legal problems. Substance dependence, commonly known as **addiction**, is characterized by the physiological and behavioral symptoms related to substance use. These symptoms include the need for increasing amounts of the substance to maintain desired effects, withdrawal if drug-taking ceases, and a great deal of time spent in activities related to substance use.

Substance abuse is more likely to be diagnosed among those who have just begun taking drugs and is often an early symptom of substance dependence. However, substance dependence can appear without substance abuse, and substance abuse can persist for extended periods of time without a transition to substance dependence.

Description

Substance abuse and dependence are disorders that affect all population groups although specific patterns of abuse and dependence vary with age, gender, culture, and socioeconomic status. According to data from the National Longitudinal Alcohol Epidemiologic Survey, 13.3% of a survey group of Americans exhibited symptoms of alcohol dependence during their lifetime, and 4.4% exhibited symptoms of alcohol dependence during the past 12 months. According to the United States Department of Health and Human Services' National Survey on Drug Use and Health, in 2005 about 9.1% of the population age 12 or older (about 22.2 million people) were classified as having substance abuse or dependence within the last year. About 7.7% (18.7 about million people) were classified as having alcohol abuse or dependence.

Although substance dependence can begin at any age, people aged 18 to 25 have been found to have higher substance abuse and dependency rates than other age groups. Individuals who first used drugs or alcohol at a young age are more likely to have drug abuse and dependence problems later in life than those who fist used drugs or alcohol at an older age. Gender proportions vary according to the class of drugs, but substance abuse and dependence is about twice as likely to occur in men than in women.

In addition to being an individual health disorder, substance abuse and dependence may be viewed as a **public health** problem with far-ranging health, economic, and social implications. Substance-related disorders are associated with teen **pregnancy** and the transmission of sexually transmitted diseases (STDs), as well as failure in school, unemployment, domestic violence, homelessness, and crimes such as **rape and sexual assault**, aggravated assault, robbery, burglary, and larceny. Many different estimates have been made for the economic cost of substance abuse and dependence, and most estimate it at tens or hundreds of billions of dollars.

The term *substance*, when discussed in the context of substance abuse and dependence, refers to medications, drugs of abuse, and toxins. These substances have an intoxicating effect, desired by the user, which can have either stimulating (speeding up) or depressive/sedating (slowing down) effects on the body. Substance dependence and/or abuse can involve any of the following 10 classes of substances:

- alcohol
- amphetamines (including "crystal meth," some medications used in the treatment of attention deficit disorder [ADD], and amphetamine-like substances found in appetite suppressants)
- cannabis (including marijuana and hashish)
- cocaine (including "crack")
- hallucinogens (including LSD, mescaline, and MDMA ["ecstasy"])
- inhalants (including compounds found in gasoline, glue, and paint thinners)
- nicotine (including that found in cigarettes and smokeless tobacco)
- opioids (including morphine, heroin, codeine, methadone, oxycodone [Oxycontin (TM)])
- phencyclidine (including PCP, angel dust, ketamine)
- sedative, hypnotic, and anxiolytic (anti-anxiety) substances (including benzodiazepines such as valium, barbiturates, prescription sleeping medications, and most prescription anti-anxiety medications)

Caffeine has been identified as a substance in this context, but as yet there is insufficient evidence to

establish whether caffeine-related symptoms fall under substance abuse and dependence.

Substances of abuse may thus be illicit drugs, readily available substances such as alcohol or glue, over-the-counter drugs, or prescription medications. In many cases, a prescription medication that becomes a substance of abuse may have been a legal, medically indicated prescription for the user, but the pattern of use diverges from the use prescribed by the physician.

Causes and symptoms

Causes

The causes of substance dependence are not well established, but three factors are believed to contribute to substance-related disorders: genetic factors, psychopathology, and social learning. In genetic epidemiological studies of **alcoholism**, the probability of identical twins both exhibiting alcohol dependence was significantly greater than with fraternal twins, thus suggesting a genetic component in alcoholism. It is unclear, however, whether the genetic factor is related to alcoholism directly, or whether it is linked to other psychiatric disorders that are known to be associated with substance abuse. For example, there is evidence that alcoholic males from families with **depressive disorders** tend to have more severe courses of substance dependence than alcoholic men from families without such family histories.

These and other findings suggest substance abuse may be a way to relieve the symptoms of a psychological disorder. In this model, unless the underlying pathology is treated, attempts to permanently stop substance dependence are ineffective. Psychopathologies that are associated with substance dependence include antisocial personality disorder, **bipolar disorder**, depression, **anxiety** disorder, and **schizophrenia**.

A third factor related to substance dependence is social environment. In this model, drug-taking is essentially a socially learned behavior. Local social norms determine the likelihood that a person is exposed to the substance and whether continued use is reinforced. For example, individuals may, by observing family or peer role models, learn that substance use is a normal way to relieve daily stresses. External penalties, such as legal or social sanctions, may reduce the likelihood of substance abuse.

At the level of neurobiology, it is believed that substances of abuse operate through similar pathways in the brain. The chemical changes induced by the stimulation of these pathways by initial use of the substance lead to the desire to continue substance use, and eventually to substance dependence.

Symptoms

The DSM-5 identifies seven criteria (symptoms), at least three of which must be met during a given 12-month period, for the diagnosis of substance dependence:

- Tolerance, as defined either by the need for increasing amounts of the substance to obtain the desired effect or by experiencing less effect with extended use of the same amount of the substance.
- Withdrawal, as exhibited either by experiencing unpleasant mental, physiological, and emotional changes when drug-taking ceases or by using the substance as a way to relieve or prevent withdrawal symptoms.
- Longer duration of taking substance or use in greater quantities than was originally intended.
- Persistent desire or repeated unsuccessful efforts to stop or lessen substance use.
- A relatively large amount of time spent in securing and using the substance, or in recovering from the effects of the substance.
- Important work and social activities reduced because of substance use.
- Continued substance use despite negative physical and psychological effects of use.

Although not explicitly listed in the DSM-5 criteria, "craving," or the overwhelming desire to use the substance regardless of countervailing

WWW.BOOKBAZ.IR

forces, is a universally-reported symptom of substance dependence.

Symptoms of substance abuse, as specified by DSM-5, include one or more of the following occurring during a given 12-month period:

- Substance use resulting in a recurrent failure to fulfill work, school, or home obligations (such as work absences, substance-related school suspensions, or neglect of children).
- Substance use in physically hazardous situations such as driving or operating machinery.
- Substance use resulting in legal problems such as drug-related arrests.
- Continued substance use despite negative social and relationship consequences of use.

In addition to the general symptoms, there are other physical signs and symptoms of substance abuse that are related to specific drug classes:

- Signs and symptoms of alcohol intoxication include such physical signs as slurred speech, lack of coordination, unsteady gait, memory impairment, and stupor, as well as behavior changes shortly after alcohol ingestion, including inappropriate aggressive behavior, mood volatility, and impaired functioning.
- Amphetamine users may exhibit rapid heartbeat, elevated or depressed blood pressure, dilated (enlarged) pupils, weight loss, excessively high energy levels, inability to sleep, confusion, and occasional paranoid psychotic behavior.
- Cannabis users may exhibit red eyes with dilated pupils, increased appetite, dry mouth, and rapid pulse. They may also be sluggish and slow to react.
- Cocaine users may exhibit rapid heart rate, elevated or depressed blood pressure, dilated pupils, and weight loss, in addition to wide variations in their energy level, severe mood disturbances, psychosis, and paranoia.
- Users of hallucinogens may exhibit anxiety or depression, paranoia, and unusual behavior in response to hallucinations (imagined sights, voices, sounds, or smells that appear real). Signs include dilated pupils, rapid heart rate, tremors, lack of coordination, and sweating. Flashbacks, or the re-experiencing of a hallucination long after stopping substance use, are also a symptom of hallucinogen use.
- Users of inhalants experience dizziness, spastic eye movements, lack of coordination, slurred speech, and slowed reflexes. Associated behaviors may include belligerence, tendency toward violence, apathy, and impaired judgment.
- Opioid drug users exhibit slurred speech, drowsiness, impaired memory, and constricted (small) pupils. They may appear slowed in their physical movements.
- Phencyclidine users exhibit spastic eye movements, rapid heartbeat, decreased sensitivity to pain, and lack of muscular coordination. They may show belligerence, predisposition to violence, impulsiveness, and agitation.
- Users of sedative, hypnotic, or anxiolytic drugs show slurred speech, unsteady gait, inattentiveness, and impaired memory. They may also display inappropriate behavior, mood volatility, and impaired functioning.

Other signs are related to the form in which the substance is used. For example, heroin, certain other opioid drugs, and certain forms of cocaine may be injected. A person using an injectable substance may have "track marks" (outwardly visible signs of the site of an injection, with possible redness and swelling of the vein in which the substance was injected). Furthermore, poor judgment brought on by substance use can result in the injections being made under dangerously unhygienic conditions. These unsanitary conditions and the use of shared needles are risk factors for major infections of the heart, as well as infection with HIV (the virus that causes **AIDS**), certain forms of hepatitis (a liver infection), and **tuberculosis**.

Cocaine is often taken as a powdery substance, which is "snorted" through the nose. This can result in frequent nosebleeds, sores in the nose, and even erosion (an eating away) of the nasal septum (the structure that separates the two nostrils).

Overdosing on a substance is a frequent complication of substance abuse. **Drug overdose** can be purposeful (with **suicide** as a goal), or due to carelessness, the unpredictable strength of substances purchased from street dealers, the mixing of more than one type of substance, or as a result of the increasing doses that a person must take to experience a similar level of effect. Substance overdose can be a life-threatening emergency, with the specific symptoms depending on the type of substance used. Substances with depressive effects may dangerously slow the breathing and heart rate, drop the body temperature, and result in general unresponsiveness. Substances with stimulatory effects may dangerously increase the heart rate and blood pressure, produce abnormal heart rhythms, increase body temperature, induce seizures, and cause erratic behavior.

Diagnosis

Tools used in the diagnosis of substance dependence include screening questionnaires and patient histories, **physical examination**, and laboratory tests. A simple and popular screening tool is the CAGE questionnaire. CAGE refers to the first letters of each word that forms the basis of each of the four questions of the screening exam:

- Have you ever tried to Cut down on your substance use?
- Have you ever been Annoyed by people trying to talk to you about your substance use?
- Do you ever feel Guilty about your substance use?
- Do you ever need an Eye opener (use of the substance first thing in the morning) in order to start your day?

A "yes" answer to two or more of these questions is an indication that the individual should be referred for a more thorough work-up for substance dependency or abuse.

In addition to CAGE, other screening questionnaires are available. Some are designed for particular population groups such as pregnant women, and others are designed to more thoroughly assess the severity of substance dependence. These questionnaires, known by their acronyms, include AUDIT, HSS, HSQ, PRIME-MD, ACE, TWEAK, s-MAST, and SADD. There is some variability among questionnaires in terms of how accurately and comprehensively they can identify individuals as substance dependent.

Patient history, as taken through the direct interview, is important for identifying physical symptoms and psychiatric factors related to substance use. Family history of alcohol or other substance dependency is also useful for diagnosis.

A physical examination may reveal signs of substance abuse. These signs are specific to the substances used, and may include needle marks, tracks, or nasal erosion.

With the individual's permission, substance use can be detected through laboratory testing of his or her blood, urine, or hair. Laboratory testing, however, may be limited by the sensitivity and specificity of the testing method, and by the time elapsed since the person last used the drug.

One of the most difficult aspects of diagnosis involves overcoming the patient's denial. Denial is a psychological state during which a person is unable to acknowledge the (usually negative) circumstances of a situation. In this case, denial leads individuals to underestimate the degree of their substance use and of the problems associated with the substance use.

Treatment

According to the American Psychiatric Association, there are three goals for the treatment of people with substance use disorders: (1) the patient abstains from or reduces the use and effects of the substance; (2) the patient reduces the frequency and severity of relapses; and (3) the patient develops the psychological and emotional skills necessary to restore and maintain personal, occupational, and social functioning.

In general, before treatment can begin, many treatment centers require that the patient undergo **detoxification**. Detoxification is the process of weaning the patient from his or her regular substance use. Detoxification can be accomplished "cold turkey," by complete and immediate cessation of all substance use, or by slowly decreasing (tapering) the dose the individual is taking, to minimize the side effects of withdrawal. Some substances must be tapered because "cold turkey" methods of detoxification are potentially life threatening. In some cases, medications may be used to combat the physical and psychological symptoms of withdrawal. For example, **methadone** is used to help patients adjust to the tapering off of heroin use.

Treatment itself consists of three parts: (1) assessment; (2) formulation of a treatment plan; (3) psychiatric management. The first step in treatment is a comprehensive medical and psychiatric evaluation of the patient. This evaluation includes:

- a history of the patient's past and current substance use, and its cognitive, psychological, physiological, and behavioral effects
- a medical and psychiatric history and examination
- a history of psychiatric treatments and outcomes
- a family and social history
- screening of blood, breath, or urine for substances
- other laboratory tests to determine the presence of other conditions commonly found with substance use disorders

After the assessment is made, a treatment plan is formulated. Treatment plans vary according to the needs of individual patients and can change according to how patients respond to different elements of treatment. Plans typically involve the following elements: (1) a strategy for the psychiatric management of the patient; (2) a strategy for reducing effects or use of substances, or for abstinence; (3) efforts to ensure compliance with the treatment program and to prevent

WWW.BOOKBAZ.IR

relapse; (4) treatments for other conditions associated with substance use. Initial therapy and treatment setting (hospital, residential treatment, partial hospitalization, or outpatient) decisions are made as part of the treatment plan, but because substance use disorders are considered a chronic condition requiring long-term care, these plans can and do change through the course of treatment.

The third step, psychiatric management of the patient, is the implementation of the treatment plan. Psychiatric management of the patient includes establishing a trusting relationship between clinician and patient; monitoring the patient's progress; managing the patient's relapses and withdrawal; diagnosing and treating associated psychiatric disorders; and helping the patient adhere to the treatment plan through therapy and the development of skills and social interactions that reinforce a drug-free lifestyle.

As part of the treatment process, patients typically undergo psychosocial therapy and, in some cases, pharmacologic treatment. Psychosocial therapeutic modalities include **cognitive-behavioral therapy**, behavioral therapy, individual psychodynamic or interpersonal therapy, **group therapy**, **family therapy**, and self-help groups. Pharmacologic treatment may include medications that ease withdrawal symptoms, reduce cravings, interact negatively with substances of abuse to discourage drug-taking, or treat associated psychiatric disorders.

Alternatives

The efficacy of alternative treatments for substance use disorders remains for the most part ambiguous. Some studies suggest that **acupuncture** can be used to help treat cocaine addiction. However, a 2007 meta-analysis (summary analysis of studies) found that there was no reproducible scientific data indicating that acupuncture was helpful. A similar meta-analysis reported that acupuncture also had no statistically significant effect on **smoking** cessation.

There has been movement toward examining some touted treatments in more rigorous clinical trials. In particular, there has been some interest in *Pueraria lobata*, or kudzu, an herb that has reputedly been used in Chinese medicine to treat alcoholism. Preclinical trials of an herbal formula with kudzu have shown that increased consumption of the herbal formula is associated with decreased consumption of alcohol. Toxicity studies show few ill effects of the formula, and human trials are currently being undertaken to more fully evaluate the efficacy of this treatment.

The effectiveness of electroacupuncture (the practice of acupuncture accompanied by the application of low levels of electrical current at acupuncture points) in alleviating opiate withdrawal symptoms is also being examined. Preclinical trials suggest that electroacupuncture treatment given prior to the administration of naxolone seems to alleviate the withdrawal effects of naxolone.

Prognosis

Recovery from substance use is notoriously difficult, even with exceptional treatment resources. Although relapse rates are difficult to accurately obtain, the NIAAA cites evidence that 90% of alcohol dependent users experience at least one relapse within the 4 years after treatment. Relapse rates for heroin and nicotine users are believed to be similar. Certain pharmacological treatments, however, have been shown to reduce relapse rates.

Relapses are most likely to occur within the first 12 months of having discontinued substance use. Triggers for relapses can include any number of life stresses (problems on the job or in the marriage, loss of a relationship, death of a loved one, financial stresses), in addition to seemingly mundane exposure to a place, situation, or acquaintance associated with previous substance use.

The development of adaptive life skills and ongoing drug-free social support are believed to be two important factors in avoiding relapse. The effect of the support group Alcoholics Anonymous has been intensively studied, and many studies have found that long-term sobriety appears to be positively related to Alcoholics Anonymous attendance and involvement. Support for family members in addition to support for the individual in recovery is also important. Because substance dependence has a serious impact on family functioning, and because family members may inadvertently maintain behaviors that initially led to the substance dependence, ongoing therapy and support for family members should not be neglected.

Prevention

Prevention is best aimed at teenagers and young adults aged 18–24 who are at very high risk for substance experimentation. Prevention programs should include an education component that outlines the risks and consequences of substance use and a training component that gives advice on how to resist peer pressure to use drugs.

Furthermore, prevention programs should work to identify and target children who are at relatively

Sudden cardiac death

Definition

Sudden cardiac death (SCD) is an unexpected death due to heart problems, which occurs within one hour from the start of any cardiac-related symptoms. SCD is sometimes called cardiac arrest.

Description

When the heart suddenly stops beating effectively and breathing ceases, a person is said to have experienced sudden cardiac death.

SCD is not the same as actual death. In actual death, the brain also dies. The important difference is that sudden cardiac death is potentially reversible. If it is reversed quickly enough, the brain will not die.

Sudden cardiac death is also not the same as a **heart attack**. A heart attack (myocardial infarction) is the result of a blockage in an artery which feeds the heart, so the heart becomes starved for oxygen. The part that has been starved is damaged beyond repair, but the heart can still beat effectively.

Causes and symptoms

Sudden cardiac death is usually caused by **ventricular fibrillation** (the lower chamber of the heart quivers instead of pumping in an organized rhythm). Ventricular fibrillation almost never returns to normal by itself, so the condition requires immediate intervention. **Ventricular tachycardia** can also lead to sudden cardiac death. The risk for SCD is higher for anyone with **heart disease**.

When the heart stops beating effectively and the brain is being deprived of oxygenated blood, a medical emergency exists.

Diagnosis

Diagnosis of sudden cardiac death is made when there is a sudden loss of consciousness, breathing stops, and there is no effective heart beat.

WWW.BOOKBAZ.IR

KEY TERMS

Defibrillator—A device which delivers a controlled electric shock to the heart to return it to normal beating rhythm.

Ventricular fibrillation—When the lower chamber of the heart quivers instead of pumping in an organized way.

Ventricular tachycardia—A rapid heartbeat, usually over 100 beats per minute.

Treatment

When sudden cardiac death occurs, the first priority is to establish the flow of oxygenated blood to the brain. The next priority is to restore normal rhythm to the heart. Forcing air into the mouth will get oxygen into the lungs. Compressing the chest simulates a pumping heart and will get some blood flow to the lungs, brain, and coronary arteries. This method is called **cardiopulmonary resuscitation** (CPR). When trained help arrives, they will attempt to establish a normal heart beat by using a device called a defibrillator.

If sudden cardiac death occurs outside the hospital setting, cardiopulmonary resuscitation (CPR) must begin within four to six minutes and advanced **life support** measures must begin within eight minutes, to avoid brain death. CPR requires no special medical skills and training is available for the ordinary person nationwide.

Prognosis

Sudden cardiac death is reversible in most people if treatment is begun quickly. However, of the people who are resuscitated, 40% will have another SCD within two years if they do not receive appropriate treatment for the underlying cause of the episode.

Prevention

In order to prevent sudden cardiac death, underlying heart conditions must be addressed. Medications and implantable cardioverter-defibrillators may be used.

Sudden infant death syndrome

Definition

Sudden infant death syndrome (SIDS) is the unexplained death without warning of an apparently healthy infant, usually during sleep. It is also known as crib death and cot death. According to the Centers for Disease Control and Prevention (CDC), a SIDS death is one that cannot be explained after a thorough investigation is conducted, including a complete **autopsy**, examination of the death scene, and review of the baby's clinical history. The American Academy of Pediatrics (AAP) issued a similar definition in its position paper on SIDS in 2005: SIDS is "the sudden death of an infant under 1 year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history."

Demographics

According to the CDC, SIDS is the leading cause of death among American infants between the ages of 1 and 12 months, and is the third leading cause overall of infant mortality in the United States. SIDS is responsible for about 0.9 death per 1,000 live births as of 2013; however, this figure is more than 50% lower than the figures for 1990, largely as a result of the "Back to Sleep" campaign. The CDC reports that as of 2011, more than 4,000 infants die each year in the United States "of no obvious cause." About half these deaths are attributed to SIDS, with the remainder classified as Sudden Unexplained Infant Death or SUID.

Most SIDS deaths occur in babies between 2 and 4 months of age; only 1% occur in newborns. About 80% of all SIDS deaths involve infants younger than 5 months. Boys are more likely than girls to die of SIDS; 60–70% of SIDS cases involve boys. Most SIDS deaths in North America occur during the winter and early spring, which are the peak times for respiratory infections. A recent epidemic of a viral disease in the surrounding community is associated with an increased number of SIDS cases in that area.

According to the National Institute for Child Health and Human Development (NICHD), African American babies are twice as likely as Caucasian babies to die from SIDS, and Native American and Alaska Native babies are three times as likely. The same high rates of SIDS cases that occur among Native Americans in the United States are found

among First Nations tribes in Canada and aboriginal groups in Australia and New Zealand. The reason for these differences is not yet known but may be related to other risk factors listed below.

Description

In typical SIDS cases, the parents or caregivers put the babies to bed after feeding them. Shortly thereafter, the caregivers discover the babies are dead, lying in the same position in which they were placed.

In most cases of SIDS, the parents state that the child was apparently healthy; however, some parents of infants who died of SIDS report that their babies "were not themselves" in the hours before death. In a number of cases, the parents report that the baby had **diarrhea** and **vomiting** at some point in the two weeks prior to death. Doctors do not know whether these digestive problems are related to SIDS in some way or are only coincidental.

Risk factors

Studies indicate that some mothers are at increased risk of having their child die of SIDS:

- Those who smoke during pregnancy and after childbirth.
- Those who abuse drugs or alcohol.
- Those who are underweight or suffer from malnutrition.
- Those who have children less than one year apart.
- Teenage mothers. The more children the mother has while still in her teens, the greater the risk of SIDS.
- Those who are obese.

Apart from sleeping position, some babies are at increased risk of SIDS:

- Babies who are born prematurely.
- Babies who weigh 4 pounds or less at birth.
- Babies who are not breastfed.
- Babies born during the fall or winter.
- Babies who had a sibling who died of SIDS.
- Babies who are part of a set of twins, triplets, or quadruplets.
- Babies who are exposed to tobacco smoke.
- Babies put to sleep in an overheated room.
- Babies whose parents practice co-sleeping (the baby shares the parents' bed at night).
- Babies who are overdressed for sleep or covered with too many blankets.

Causes and symptoms

The cause of SIDS is not yet known for certain, although at least 70 different theories have been proposed as of 2014. As of 2015, there are 29 clinical trials under way evaluating apnea, preterm birth, the use of pacifiers, sleeping position, and secondhand smoke in the home as risk factors for SIDS. It is likely that some cases of SIDS are the result of a combination of factors. Doctors have proposed several different theories for SIDS:

- Bacterial infections. A British study published in May 2008 reported that some cases of SIDS appear to result from previously undetected bacterial infections.
- Abnormalities in the part of the brain stem that controls breathing. A study published in the *Journal of the American Medical Association* in the fall of 2007 is one of the strongest pieces of evidence so far that innate differences in brain structure may put some babies at increased risk of SIDS.
- Smothering caused by sleeping on the stomach. This theory holds that babies put to sleep lying on the stomach may breathe in their own exhaled carbon dioxide because they do not have the same ability as older children to move their heads during sleep to get more oxygen.
- Episodes of apnea (sudden cessation of breathing). Babies sometimes stop breathing periodically for reasons that are still not completely understood.

KEY TERMS

Apnea—Temporary cessation of breathing. It may be intentional (holding one's breath) or involuntary, resulting from criminal assault (choking), a neurological disorder, an upper respiratory infection, or accidental trauma.

Autopsy—The examination of a body after death to determine the cause of death.

Brain stem—The lower part of the brain directly connected to the spinal cord. It controls breathing and other vital functions.

Co-sleeping—Allowing a baby to sleep in the same bed as its parents. It is also called bed sharing.

Congenital—Existing or present at the time of birth.

Crib death—Another name for SIDS. It is often called cot death in the United Kingdom, Australia, and New Zealand.

Infanticide—Intentional killing of a child within the first year of life.

Postmortem—Referring to the period following death.

- Abnormalities in heart rhythm. About 10% of babies who die of SIDS have been found to have sudden episodes of extremely rapid heartbeat.
- Triple-risk theory. This theory proposes to explain SIDS as the end result of three factors: a biological vulnerability (such as a weakened heart or abnormal brain stem), an environmental problem (such as sleeping on the stomach), and being too young to regulate breathing and other vital functions as effectively as older children.
- Genetic factors. There is evidence that 5–10% of SIDS cases are associated with genetic mutations that affect potassium channels in the heart tissue. This abnormality increases the risk of irregular heart rhythms and sudden cardiac death. Some researchers also think that the relatively high rate of SIDS among African Americans compared to other racial groups may be related to a genetic predisposition to irregular heart rhythms. Research in this area is ongoing.

Still other theories about the cause of death in SIDS include immune system disorders that cause changes in the baby's heart rate and breathing patterns during sleep, or a metabolic disorder that causes a buildup of fatty acids in the baby's system.

Theories that are no longer accepted include the notion that SIDS is caused by vaccinations, by dust mites or other insects in the crib mattress, or by toxic gases released by materials used in the manufacture of crib mattresses.

Diagnosis

The diagnosis of SIDS is primarily a diagnosis of exclusion. This means that it is given only after other possible causes of the baby's death have been ruled out. Known risk factors aid in the diagnosis. Unlike the pattern in other diseases, however, the diagnosis of SIDS can only be given postmortem. It is recommended that all infants who die in their sleep receive an autopsy to determine the cause. Autopsies indicate a definite explanation in about 20% of cases of sudden infant death. In addition, an autopsy can often put to rest any doubts the parents may have. Investigation of the location of the death is also useful in determining the child's sleeping position, bedding, room temperature, and similar factors.

The American Academy of Pediatrics (AAP) estimates that between 1% and 5% of cases of SIDS actually involve infanticide. As a result, the AAP has drawn up a list of criteria that must be met in order to distinguish a case of SIDS from child abuse:

- There has been a complete autopsy of the baby performed by a licensed medical examiner, and the autopsy findings are consistent with a diagnosis of SIDS.
- There is no evidence of head trauma or significant disease.
- There is no evidence of trauma to the baby's bones.
- Such other possible causes of death as pneumonia, metabolic disorders, dehydration, severe birth defects, massive infection, trauma to the abdomen, or carbon monoxide poisoning have been ruled out.
- There is no evidence that the baby was given alcohol, drugs, or other toxic substances.
- There is no evidence of foul play when the death scene is investigated.
- The baby's medical history does not indicate previous health problems.

Treatment

There is nothing that can be done to treat the infant when SIDS occurs. Treatment of the parents

includes support and understanding; however, the doctor and other health professionals must at the same time conduct a thorough investigation into the circumstances surrounding the baby's death. There are some differences among the states as to the way in which the postmortem (after death) investigation is carried out, but all states require an investigation before the death can be defined as SIDS. It is understandably difficult for parents to accept the need for an autopsy and an evaluation of the bed and room in which the baby died when they are grieving; unfortunately, ruling out the possibility of **abuse** or intentional suffocation of the child is a legal necessity.

Circumstances that concern doctors as well as law enforcement when a baby dies suddenly include:

- The child was 7 months of age or older. SIDS is unusual in this age group.
- The pregnancy was unwanted.
- There have been previous unexplained infant deaths in the family.
- Family members have a history of arrests for violent or intoxicated behavior.

Prevention

The NICHD and CDC recommend the following precautions to reduce the risk of SIDS:

- Infants should always be placed on their backs to sleep when they are left alone; they should be placed on their stomachs *only* when they are awake and supervised by someone responsible.
- If the baby sleeps in a crib, the crib's mattress should be firm and fit snugly into the crib frame. Such other firm sleeping surfaces as bassinets or cradles are also fine.
- The baby should be dressed in a sleeper or pajama to keep it warm rather than being covered by a blanket.
- Parents who co-sleep with a baby should *never* smoke, drink alcohol, or use drugs when sleeping with the baby. It is better to have the baby sleep in a crib or bassinet next to the parents' bed rather than sharing the bed.
- Parents should *never* put a baby on a couch, waterbed, or pillow for a nap.
- Parents should *never* smoke in the same room as the baby or allow anyone else to do so.
- Caregivers should *never* place the baby to sleep or nap with any pillows, stuffed toys, bumper pads, comforters, quilts, or sheepskins.

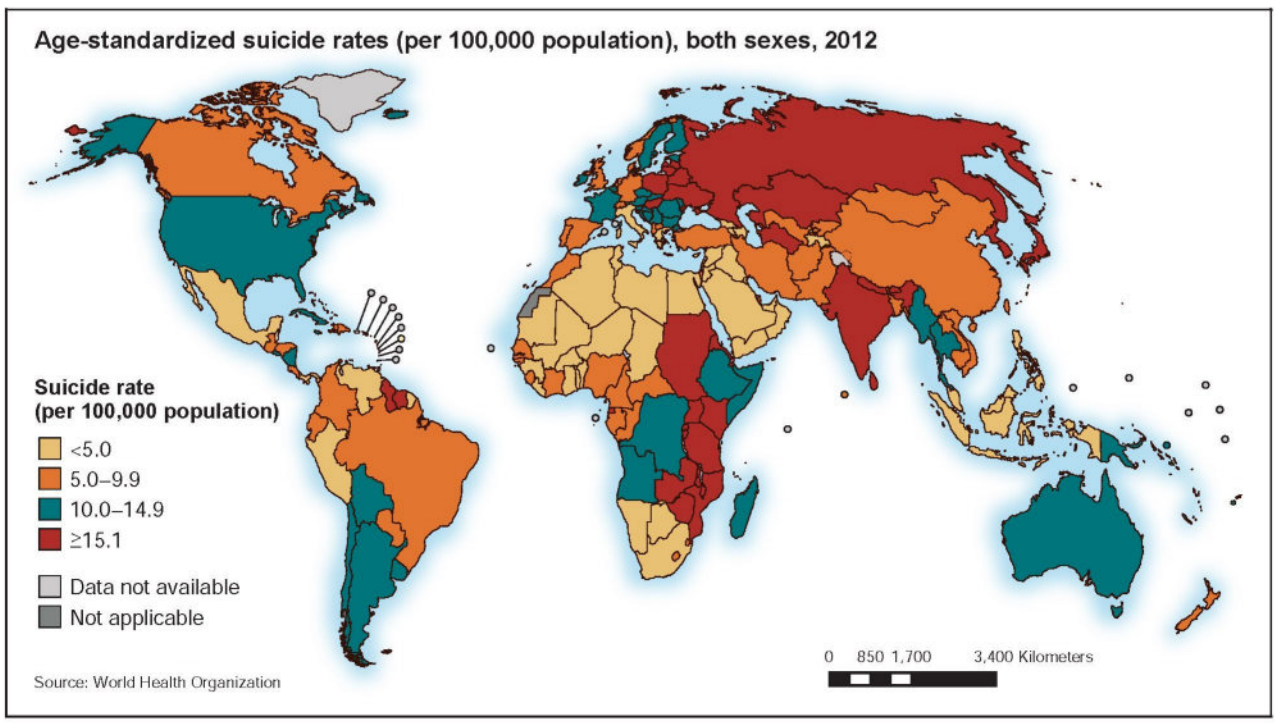
Suicide

Definition

Suicide is the intentional taking of one's own life.

Description

Suicidal behavior is usually regarded—and responded to—as a psychiatric emergency, often brought on by a mental disorder such as depression, **bipolar disorder**, **schizophrenia**, or substance abuse.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Stress or crises, such as financial or legal difficulties or a crumbling marriage, can also lead to suicide.

Attitudes toward suicide have varied throughout history and vary considerably among different cultures. The ancient Greeks considered suicide an offense against the state, whereas the Romans believed that suicide could be a noble way to die. The view of suicide as a sin prevailed in Western societies for hundreds of years. Only since the later decades of the twentieth century did suicide cease to be considered a criminal act.

There are different levels of suicidal behavior:

- completed suicide
- suicide attempts that are potentially fatal
- suicide gestures—behaviors that are not necessarily lethal but are a cry for help or attention, such as superficially cutting one's wrists
- suicide gambles—attempts in which people gamble that their lives will be saved through intervention, such as a fatal but slow-acting drug overdose
- suicide equivalents—behaviors that invoke responses similar to those seen with suicide, such as a teenager running away from home as an indirect call for help
- suicidal ideation or thinking about suicide, which can range from nonspecific thoughts that life is not worth living to specific suicide planning

Suicide raises difficult ethical issues, including an individual's right to die and the legality of assisted suicide. Life-sustaining technologies of modern medicine have intensified the debate surrounding assisted suicide for people with progressively debilitating or terminal illnesses and diminished quality of life. Assisted suicide—called self-deliverance in Britain—is the bringing about of one's own death with the help of another person, often a physician. Physician-assisted suicide is legal in the Netherlands, Belgium, and several U.S. states, including Oregon, Washington, and Vermont, and is practiced elsewhere.

Risk factors

Mental illness is a major risk factor for suicide. More than 90% of Americans who commit suicide have been diagnosed with a psychiatric illness and/or have problems with substance abuse, especially alcohol, opiates, and cocaine. Schizophrenia, bipolar disorder, and borderline and certain other **personality disorders** are risk factors. People are at particularly high risk for suicide during the first week following discharge from a psychiatric facility.

Other suicide risk factors include individuals who:

- are victimized by bullying
- are isolated from other people and community
- have a family history of suicide
- have a history of attempted suicide
- have a history of childhood abuse or family violence
- have had traumatic experiences
- have experienced stressful events, such as separation or divorce, job loss, or death of a spouse
- have a chronic or progressively debilitating disease or condition; chronic, severe, or intractable pain; or loss of mobility or independence
- have access to a firearm
- are victims of alcohol or substance abuse, which weakens impulse control
- have low total serum cholesterol
- reside at a higher altitude, possibly due to altitude-related metabolic stress in individuals with mood disorders
- are involved with the criminal justice system, or are incarcerated (especially during the first hours or week of imprisonment)
- have sleep problems and disorders
- are impulsive
- have been exposed to suicidal behavior in others, including family members, peers, or friends (especially among adolescents) or celebrities, which is referred to as contagion
- take certain medications
- live in low-income households or in poverty
- are unmarried
- are lesbian/gay/bisexual/transgender (LGBT)

Demographics

Suicide is a leading cause of death worldwide, with more than 800,000 suicides annually, according to the World Health Organization. Among all age groups, suicide was the fifteenth leading cause of death worldwide in 2012, but among those aged 15–29, it was the second leading cause of death.

According to the U.S. Centers for Disease Control and Prevention (CDC), 40,600 suicides were reported for 2012, making suicide the tenth leading cause of death in the United States. The suicide rate in the United States has hovered between a low of 10.4 per 100,000 in 2000 to 13 per 100,000 in 1986. The highest suicide rate was among middle-aged people 45–64 years old at 19.1/100,000 in 2012, followed by those in the 85-years-old-and-up age group at 17.8/100,000. The

WWW.BOOKBAZ.IR

suicide rate for those less than 14 years old was 0.5/100,000, and for those 14–24, it was 11.1/100,000 in 2012.

The suicide rate for men in 2012 was nearly four times higher among males than females (20.3/100.000 vs. 5.4/100,000, respectively). For every one death linked to suicide, the CDC estimates that approximately 12 people harm themselves (shootings, hangings, etc.) to an extent that they require hospitalization. Many attempts likely go untreated and unreported, so the true number of attempted suicides may be much higher.

Suicide occurs among all populations and across all walks of life. Although three times more females than males attempt suicide, four times as many males complete suicide. This is because men tend to use more lethal methods, such as firearms, whereas women tend to choose methods such as drug overdoses or poison that allow more opportunity for intervention. In the United States in 2012, suicide rates were much higher among whites and American Indians/Alaskan Natives than among other groups. Although in the past, soldiers had a below-average suicide rate, in recent years, suicides among U.S. Army personnel have increased significantly. Suicide rates are generally highest in the spring; however, regions with long, dark winters, such as Scandinavia, have high suicide rates, possibly due to depression associated with lack of daylight (**seasonal affective disorder**).

Causes and symptoms

Causes

Suicide results from combinations of factors specific to each individual. Studies have found a connection between genetic factors and suicide. Many mental disorders that are risk factors for suicide, such as bipolar disorder, are strongly associated with genetic factors. Genes related to the expression of the neurotransmitter serotonin have been implicated in second suicide attempts. Changes in gene expression have also been associated with suicide: Autopsies of suicide victims have found extensive changes in DNA methylation patterns that affect gene expression in the hippocampus of the brain.

Some suicides appear to be impulsive acts, whereas others follow a major life event or crisis. However, the most common trigger is the **pain** and desperation of a mental illness, often unrecognized and untreated depression or bipolar disorder. A complex of illnesses involving changes in the brain, depression is very common in the general population. It may be associated with a major life change—either positive or negative—or a serious illness, or it may occur without obvious cause. Alcohol, drugs, and some medications can contribute to depression, and alcohol is a factor in 25–30% of suicides. Substance abuse can lead to suicide during intoxication, chronic use, or withdrawal, especially when combined with depression. People in recovery programs are often at particular risk. Many people with depression develop **anxiety disorders**, which can further contribute to suicidal thoughts or behaviors. Depression is particularly dangerous when the individual is emerging from the darkest depths of the disease and has the energy to act upon suicidal impulses.

Other mental disorders that may be associated with suicidal behavior are:

- early-onset bipolar disorder
- schizophrenia, which can cause depression or so-called command hallucinations in which voices order a person to commit suicide
- bulimia nervosa
- anxiety disorders, including obsessive-compulsive disorder, and phobic disorders such as social phobia
- delirium
- dementia
- personality disorders
- postpartum depression
- seasonal affective disorder (SAD)
- traumatic brain injury (TBI), especially multiple TBIs
- post-traumatic stress disorder (PTSD), which affects large numbers of combat veterans, as well as survivors of childhood sexual abuse, physical/emotional abuse, or physical devastation

Societal factors have been identified as contributing to suicide rates in the United States. These include:

- stresses on the nuclear family, such as divorce and economic hardship
- erosion of a common set of moral values
- weakening of churches, synagogues, neighborhoods, and other mid-range social groups that provide a sense of belonging
- frequent geographic moves that interfere with long-term relationships
- sensationalized and irresponsible reporting of suicide in the mass media that increases the risk of contagion or copycat suicides, particularly among impressionable adolescents
- readily available medications that facilitate relatively painless death

- availability of lethal methods, especially firearms and certain bridges and tall buildings that are so-called suicide magnets

A number of prescription medications, including some antidepressants, anticonvulsants, and **analgesics**, have been linked to suicidal behavior and require warning labels. Smoking-cessation medications and glucocorticoids may also increase the risk of suicidal behavior.

Symptoms

Suicidal depression is not always obvious. For example, some depressed men appear irritable or angry rather than depressed. "IS PATH WARM?" is a mnemonic for signs of suicidal behavior:

- I—ideation
- S—substance abuse
- P—purposelessness
- A—anxiety
- T—trapped
- H—hopelessness
- W—withdrawal
- A—anger
- R—restlessness
- M—mood changes

Other signs of suicidal intentions are:

- isolation or withdrawal
- emotional distancing
- lack of family or friends
- distraction, seeming to be in one's own world
- lacking any sense of humor
- dwelling on the past, especially losses and failures
- feelings of hopelessness and helplessness
- preoccupation with death

People at acute risk may talk or write about self-harm or suicide or threaten self-harm. They may look for the means, such as firearms or pills. They may write or revise a will, put their house and affairs in order, unexpectedly visit family and friends, or compose a suicide note. A surprising number of people visit their primary care physician within a month of committing suicide.

Most children and adolescents who attempt suicide are trying to escape psychological pain or unbearable circumstances, gain attention, influence others, or communicate strong feelings. Common triggers of suicidal behavior are interpersonal conflict or loss, most often involving parents or a romantic attachment. Family discord, physical or **sexual abuse**, disciplinary actions, or other crises are usually associated with attempted or completed suicide. Although most serious suicide attempts involve suicide notes, show evidence of planning, and utilize lethal methods, adolescent attempts are usually of relatively low intent and lethality, since only a minority of such teens actually want to die.

Signs and symptoms of suicidal tendencies in teens are similar to those of depression:

- violent or rebellious behaviors or running away
- physical aggression or destructive behaviors
- consistent rule breaking
- changes in eating and sleeping patterns
- withdrawal from family, friends, and activities
- drug or alcohol use
- neglect of personal appearance
- personality changes
- boredom, poor concentration, declining schoolwork quality
- vague physical complaints, such as stomachaches, headaches, or fatigue
- intolerance of rewards or praise

Teens who are planning suicide may

- say they are a bad person or feel rotten inside
- give verbal hints, such as claiming they will not be a problem for others much longer
- give or throw away possessions, or clean their room
- become suddenly cheerful after a period of depression
- experience hallucinations or bizarre thoughts

Diagnosis

Examination

Suicidal behaviors are often diagnosed because the patient seeks help in an emergency department, or because family members or first responders take the patient there. The patient may have written a suicide note, talked about intentions, or begun to implement a suicide plan. Suicide attempts are treated as psychiatric emergencies. They require a mental status review, detailed assessment of the circumstances surrounding the attempt, and a complete psychiatric evaluation.

A mental status review includes:

- appearance—the patient's clothing, personal hygiene, and any physical evidence of self-harm
- affect—expression, emotion, and intonation when describing plans for self-destructive behavior

WWW.BOOKBAZ.IR

- thoughts—suicide command hallucinations (usually auditory); delusions about the benefits of suicide, such as thoughts that relatives will be better off after the person dies; and obsession with suicide
- homicidal potential
- judgment, insight, and intellect
- orientation and memory, including signs of delirium or dementia

The need for suicide intervention is assessed by the following:

- ideation—whether the patient has thoughts of self-harm
- plans—the more specific the suicide plan, the greater the risk
- purpose—what the patient believes will be achieved by suicide
- potential for homicide

The clinician will also evaluate risk factors as described above.

Treatment

Immediate suicide intervention includes having someone stay with the patient and removing anything that could be used for self-harm. Patients who have attempted suicide or are at risk are kept under observation in a safe, secure, highly supervised setting. Medications for underlying mental disorders, including antidepressants or antipsychotics, are used to treat patients at risk for suicide.

People who have attempted suicide and are considered a serious danger to themselves or others can be legally hospitalized against their will. The decision to hospitalize is based on the severity of the patient's depression or agitation; the presence of risk factors, including a history of previous suicide attempts, substance abuse, recent stressful events, or symptoms of **psychosis**; and the availability of friends, relatives, or other social support. The patient may be released following the psychiatric assessment if the attempt is judged to have been a nonlethal suicide gesture and the patient has adequate outside support. An ongoing treatment management plan is initiated, usually involving a combination of antidepressant medications and **psychotherapy**.

Suicidal teens are typically asked to sign a no-suicide contract, in which the patient promises to refrain from self-destructive behavior and to notify the healthcare professional or caregiver of any suicidal feelings. Treatment of a suicidal young person includes:

- removal of firearms and dangerous medications from the home
- continuous treatment of the underlying psychiatric disorders
- development of social and problem-solving skills
- evaluation of home and school environments
- family education around psychiatric problems and suicide risk

In addition to grief, survivors of a friend or relative's suicide may struggle with feelings of guilt and shame. Survivors often benefit from group or individual psychotherapy to work through issues such as whether they could have prevented the suicide or whether they are themselves at risk for suicide. Increasing numbers of clergy, as well as mental health professionals, pursue advanced training in counseling survivors of suicide.

Alternatives

Exposure psychotherapy is an often-effective treatment for PTSD due to recent **trauma**. The behavioral psychologist has the patient repeatedly recall and confront the traumatic event. With each recollection, the memory is edited through a process called memory reconsolidation. The details of the memory gradually become uncoupled from **anxiety** and panic attacks. Repeated sessions may lead to memory extinction. Exposure psychotherapy, however, is only effective for recent memories.

Prognosis

In the first year after a suicide attempt, the risk of completed suicide is 80 times higher than average for women, 200 times higher for men and anyone over 45, and 300 times higher for white men over 65. Nevertheless, the prognosis following attempted suicide is generally favorable: Most studies have found that less than 10% of people who attempt suicide once will eventually die by suicide. This indicates that most suicidal behaviors are temporary responses to acute crises rather then reflections of permanent states of mind. However, people who attempt suicide and rate highly on measures of hopelessness and intent are more likely later complete suicide.

Prevention

Although suicides can be difficult to predict and prevent, most are potentially preventable. About 30–40% of people who die by suicide made a previous attempt. Many people change their minds if they can be helped through their immediate crisis. Some people

KEY TERMS

Assisted suicide—Voluntarily ending one's life with the help of a physician, relative, or friend, usually in the face of terminal illness.

Bipolar disorder—A mood disorder characterized by periods of excessive excitability and energy alternating with periods of depression and lack of energy.

Command hallucinations—Hallucinations, usually auditory, in which a person is commanded to commit an act such as suicide.

Depression—A mental condition characterized by extreme sadness and loss of interest in life and problems with appetite, sleep, concentration, and daily functioning; severe depression can lead to suicide attempts.

Hippocampus—A region of the brain that is important for forming, storing, and processing memory.

Ideation—The formulating or entertaining of ideas, such as the idea of committing suicide.

Post-traumatic stress disorder (PTSD)—Ongoing psychological responses to a highly stressful event; typically characterized by depression, anxiety, flashbacks, nightmares, and avoidance of reminders of the traumatic experience.

Schizophrenia—A psychotic disorder characterized by loss of contact with one's environment, deterioration of everyday functioning, and personality disintegration.

Seasonal affective disorder (SAD)—Depression that recurs as the days grow shorter in fall and winter.

Serotonin—A chemical in the brain, blood, and stomach membrane that transmits signals across the gaps between nerve cells; abnormally low serotonin levels are associated with depression and an increased risk of suicide.

Suicide gesture—Attempted suicide by a low-lethality method, with a low level of intent or planning and only minor physical damage; sometimes called pseudocide.

Suicide magnet—A bridge, tall building, or geographic location that acquires a reputation for suicides and suicide attempts.

Traumatic brain injury (TBI)—Damage to the brain from sudden trauma.

change their minds during the actual attempt; for example, many people who have survived jumping from the Golden Gate Bridge have later reported that they regretted their action even as they were falling and were grateful to have survived.

Recognizing the potential for suicide is crucial. An estimated 67% of all adults and 80% of seniors who completed suicide visited a physician within a month of their death. The ability of primary-care physicians to evaluate their patients for depression and to identify suicidal patients and intervene is of the utmost importance. Depression can often be effectively treated through a combination of antidepressants and psychotherapy.

Most people give clear warnings of their suicidal thoughts; however, those around them may not recognize the significance or may not know how to respond. People who are concerned that a family member or friend is at risk for suicide should do the following:

- educate themselves about warning signs and risk factors
- identify healthcare professionals who know the person and can help
- call 911 or the local emergency number if the person seems to be at immediate risk

Factors that lower the risk of adult suicide include:

- a significant friendship network outside of the workplace
- a stable marriage
- a close-knit extended family
- religious faith and practice, especially religions that value life and discourage suicide
- a strong interest in or commitment to a project or cause that encourages social interaction and cohesion

Sulfonamides

Definition

Sulfonamides are medicines that prevent the growth of bacteria in the body.

Purpose

Sulfonamides are used to treat many kinds of infections caused by bacteria and certain other microorganisms. Physicians may prescribe these drugs to treat urinary tract infections, ear infections, frequent or long-lasting **bronchitis**, bacterial **meningitis**, certain eye infections, *Pneumocystis carinii*pneumonia, traveler's **diarrhea**, and a number of other kinds of infections. These drugs will *not* work for colds, flu, and other infections caused by viruses.

Description

Sulfonamides, also called sulfa medicines, are available only with a physician's prescription. They are sold in tablet and liquid forms. Some commonly used sulfonamides are sulfisoxazole (Gantrisin) and the combination drug sulfamethoxazole and trimethoprim (Bactrim, Cotrim).

Recommended dosage

The recommended dosage depends on the type of sulfonamide, the strength of the medicine, and the medical problem for which it is being taken. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage.

Always take sulfonamides exactly as directed. To make sure the infection clears up completely, take the medicine for as long as it has been prescribed. Do not stop taking the drug just because symptoms begin to improve. Symptoms may return if the drug is stopped too soon.

Sulfonamides work best when they are at constant levels in the blood. To help keep levels constant, take the medicine in doses spaced evenly through the day and night. Do not miss any doses. For best results, take the medicine with a full glass of water and drink several more glasses of water every day. This will help prevent some of the medicine's side effects.

Precautions

Symptoms should begin to improve within a few days of beginning to take this medicine. If they do not, or if they get worse, check with the physician who prescribed the medicine.

Although such side effects are rare, some people have had severe and life-threatening reactions to sulfonamides. These include sudden, severe liver damage, serious blood problems, breakdown of the outer layer of the skin, and a condition called Stevens-Johnson syndrome, in which people get blisters around the mouth, eyes, or anus. Call a physician immediately if any of these signs of a dangerous reaction occur:

- skin rash or reddish or purplish spots on the skin
- other skin problems, such as blistering or peeling
- fever
- sore throat
- cough
- shortness of breath
- joint pain
- pale skin
- yellow skin or eyes

This medicine may cause **dizziness**. Anyone who takes sulfonamides should not drive, use machines or do anything else that might be dangerous until they have found out how the drugs affect them.

Sulfonamides may cause blood problems that can interfere with healing and lead to additional infections. Avoid injuries while taking this medicine. Be especially careful not to injure the mouth when brushing or flossing the teeth or using a toothpick. Do not have dental work done until the blood is back to normal.

This medicine may increase sensitivity to sunlight. Even brief exposure to sun can cause a severe **sunburn** or a rash. While being treated with this medicine, avoid being in direct sunlight, especially between 10 a.m. and 3 p.m.; wear a hat and tightly woven clothing that covers the arms and legs; use a sunscreen with a skin protection factor (SPF) of at least 15; protect the lips with a sun block lipstick; and do not use **tanning** beds, tanning booths, or sunlamps.

Babies under 2 months should not be given sulfonamides unless their physician has ordered the medicine.

WWW.BOOKBAZ.IR

Older people may be especially sensitive to the effects of sulfonamides, increasing the chance of unwanted side effects, such as severe skin problems and blood problems. Patients who are taking water pills (**diuretics**) at the same time as sulfonamides may also be more likely to have these problems.

Special conditions

People with certain medical conditions or who are taking certain other medicines can have problems if they take sulfonamides. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to sulfonamides, water pills (diuretics), diabetes medicines, or **glaucoma** medicine in the past should let his or her physician know before taking sulfonamides. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. In studies of laboratory animals, some sulfonamides cause **birth defects**. The drugs' effects on human fetuses have not been studied. However, pregnant women are advised not to use this medicine around the time of labor and delivery, because it can cause side effects in the baby. Women who are pregnant or who may become pregnant should check with their physicians about the safety of using sulfonamides during **pregnancy**.

BREASTFEEDING. Sulfonamides pass into breast milk and may cause liver problems, anemia, and other problems in nursing babies whose mothers take the medicine. Because of those problems, women should not breastfeed when they are under treatment with this drug. Women who are **breastfeeding** and who need to take this medicine should check with their physicians to find out how long they need to stop breastfeeding.

OTHER MEDICAL CONDITIONS. Before using sulfonamides, people with any of these medical problems should make sure their physicians are aware of their conditions:

- anemia or other blood problems
- kidney disease
- liver disease
- asthma or severe allergies
- alcohol abuse
- poor nutrition
- abnormal intestinal absorption
- porphyria
- folic acid deficiency
- deficiency of the enzyme glucose-6-phosphate dehydrogenase (G6PD)

USE OF CERTAIN MEDICINES. Taking sulfonamides with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Side effects

The most common side effects are mild diarrhea, nausea, **vomiting**, dizziness, **headache**, loss of appetite, and tiredness. These problems usually go away as the body adjusts to the drug and do not require medical treatment.

More serious side effects are not common, but may occur. If any of the following side effects occur, check with a physician immediately:

- itching or skin rash
- reddish or purplish spots on the skin
- other skin problems, such as redness, blistering, peeling
- severe, watery or bloody diarrhea
- muscle or joint aches
- fever
- sore throat
- cough
- shortness of breath
- unusual tiredness or weakness
- unusual bleeding or bruising
- pale skin
- yellow eyes or skin
- swallowing problems

Other rare side effects may occur. Anyone who has unusual symptoms while taking sulfonamides should get in touch with his or her physician.

Interactions

Sulfonamides may interact with a large number of other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Individuals who take sulfonamides should let their physician know all other medicines they are taking. Among the drugs that may interact with sulfonamides are:

- acetaminophen (Tylenol)
- medicine for overactive thyroid
- male hormones (androgens)
- female hormones (estrogens)
- other medicines used to treat infections

Sunburn

Definition

Sunburn is damage to the skin occurring as a result of overexposure to the sun's natural ultraviolet (UV) rays or artificially made UV radiation from suntan beds and other such devices. Sunburn, which is a form of a radiation burn, is usually noticeable within three hours after exposure and results in red, painful skin that may feel warm to the touch. The condition generally takes several days to heal and may result in blistering or peeling of the skin. Extended UV exposure, especially repeated experiences of sunburn, can lead to certain diseases of the skin including **skin cancer**.

Description

Sunburn is caused by exposure to the ultraviolet (UV) rays of the sun or from those UV rays produced artificially. There are two types of ultraviolet rays—UVA and UVB—that can cause problems with the skin. UVA rays penetrate the skin more deeply and can cause **melanoma** in susceptible people. UVB rays, which do not penetrate as deeply, cause sunburn and wrinkling. Most UVB rays are absorbed by **sunscreens**, but only about half the UVA rays are absorbed.

First-degree burning of the skin may occur with sunburn. In first-degree sunburn, **pain**, redness, and some swelling may be experienced, and the skin may feel warm when touched. The symptoms of second-degree sunburn may result after more prolonged sun exposure and when negligible or no sunscreen has been used to prevent Sun damage. The symptoms of second-degree sunburn include the symptoms of first degree (pain, redness, swelling, hot to the touch) wherein the symptoms are more severe and include blistering of the skin. In second-degree sunburn, deeper layers of the skin including nerve endings have been damaged. This degree of sunburn takes longer to heal than first-degree burning.

Sometimes the term sun **poisoning** is used; however, the sun does not actually poison the skin. Sun poisoning refers to a very severe case of sunburn in which overexposure to ultraviolet radiation causes all the symptoms of sunburn (redness, pain, swelling, warmth, blistering) along with **fever**, chills, **headache**, nausea, and/or **dizziness**. **Dehydration** is also a common factor in severe cases of sunburn, or sun poisoning.

WWW.BOOKBAZ.IR

This person has a second-degree sunburn on the back of the neck. *(Custom Medical Stock Photo, Inc.)*

Fair-skinned people are most susceptible to sunburn because their skin produces only small amounts of the protective pigment called melanin. People trying to get a tan too quickly in strong sunlight are also more vulnerable to sunburn. Although they have a lower risk, even the darkest-skinned people can get skin cancer.

Repeated sun overexposure and burning can prematurely age the skin, causing yellowish, wrinkled skin. Overexposure can increase the risk of skin cancer, especially a serious burn in childhood.

Demographics

Skin cancer from sun overexposure is a serious health problem in the United States, causing over 3.5 million cases in more than 2 million Americans each year. In fact, the Skin Cancer Foundation (SCF) states that skin cancer is the most common type of cancer in the United States, with skin cancer happening more often than the combined cancers of the breast, colon, lung, and prostate. Specifically, one in five Americans will get skin cancer at some point in their lives.

The most serious type of skin cancer, melanoma, becomes twice as likely after five or more sunburns. Unfortunately, a SCF survey found that 42% of people become sunburned at least once a year. Further, approximately 90% of nonmelanoma skin cancers are associated with exposure to the sun's ultraviolet radiation.

The most frequent form of skin cancer is **basal cell carcinoma**. According to the SCF, it affects about 2.8 million Americans each year. Although this type of skin cancer is rarely fatal, it can be quite disfiguring to the skin. The second most frequent form of skin cancer is squamous cell carcinoma. About 700,000 cases are diagnosed each year in the United States. Of these two skin cancers—basal cell carcinoma and squamous cell carcinoma—are common, and between 40% and 50% of American adults who live to the age of 65 years will get one or the other of these cancers at least once.

Causes and symptoms

The ultraviolet rays in sunlight destroy cells in the outer layer of the skin, damaging tiny blood vessels underneath. When the skin is burned, the blood vessels dilate and leak fluid. Cells stop making protein. The ultraviolet rays damage their deoxyribonucleic acid (DNA). Repeated DNA damage can lead to cancer.

When the sun **burns** the skin, it triggers immune defenses, which identify the burned skin as foreign. At the same time, the sun transforms a substance on the skin that interferes with this immune response. While this substance keeps the immune system from attacking a person's own skin, it also means that any malignant cells in the skin will be able to grow freely.

Sunburn causes skin to turn red and blister. Several days later, the dead skin cells peel off. In severe cases, the burn may occur with sunstroke (**vomiting**, fever, and collapse).

Beyond pain, redness, swelling, warmth-to-the-touch, and blistering, UV radiation can lead to other physical complications. Repeated UV exposure leads to **aging**, spotting, and wrinkling of the skin, known as photoaging. Skin spots—also called age spots, liver spots, or solar lentigines—result after years of prolonged ultraviolet light exposure when the melanin of the epidermis becomes clustered together or is produced by skin cells in high concentrations.

A condition known as actinic keratosis—or solar keratosis—may arise after repeated natural Sun or artificial UV exposure. An actinic keratosis is a rough, dry, scaly, or warty patch of skin usually appearing on the face, hands, arms, or shoulders—areas of the body most exposed to the sun. An actinic keratosis usually begins as a small spot or patch and generally takes several years to develop. These patches are usually treated as precancerous, however, as they frequently result in malignancy.

Damage to the eyes is a complication of exposure to ultraviolet light, either by sunlight or **tanning** beds or bulbs. Inflammation to the cornea, known as photokeratitis, and inflammation to the conjunctiva, called photoconjunctivitis, may result. These conditions are usually temporary and can easily be prevented with protective eyewear—UV-filtered sunglasses.

Long-term effects to the eye caused by exposure to ultraviolet light may also result. One such consequence of repeated UV exposure to the unprotected eye is **cataracts**. Cataracts form when the lens and the transparent layer surrounding the lens become increasingly clouded and opaque. Cataracts impair vision and may lead to blindness.

Another consequence of UV radiation overexposure on the eyes is **pterygium**, a condition in which thickened conjunctiva grows from the inner side of the eyeball usually covering part of the cornea. The mass of conjunctiva is usually fleshy and creamy in nature, and results in inhibited vision.

Overexposure to ultraviolet radiation has been linked to immune suppression. Low doses of UVB exposure (those UV rays that have wavelengths from 315 to 280 nanometers) can compromise the immunological response of animals and humans, and excessive UVB exposure can lead to overall immunological suppression. When immunity is compromised by ultraviolet radiation, the skin's ability to respond to allergic triggers and other compromising factors are limited. People with the herpes simplex virus experience a greater number of outbreaks of **cold sores** after exposure to UV radiation.

The leading cause of skin cancer is exposure to UV radiation, especially a history of repeated or prolonged exposures. Sun over-exposure in childhood and adolescence is linked to the occurrence of skin cancer later in life. The World Health Organization (WHO) reports that one in three diagnosed cancers is a skin cancer; the most fatal of these is malignant melanoma.

Skin cancers are classified under two types: melanomas and nonmelanomas. Melanomas are formed when changes occur to melanocytes—cells of the epidermis responsible for the production of melanin. Basil cell carcinoma is linked to ultraviolet radiation and is a nonmelanoma. It is the most common form of skin cancer in the United States where, according to the American Cancer Society, 75% of all cases of skin cancer are basil cell carcinomas.

The majority of basil cell carcinomas occur on areas of the skin that commonly receive sun exposure—the face, neck, forearms, shoulders, tops of the hands, or scalp. These skin cancers grow slow and are painless and develop in the epidermis, that is, top cell layer of the skin. Basil cell carcinomas may appear as a new skin growth that does not heal or that bleeds frequently or easily.

At one time basil cell carcinomas were common in people over the age of 40 years, but in the late twentieth and early twenty-first century they were appearing in younger people. People with fair skin, light colored eyes (blue or green), lighter colored hair (blonde or red), and those who are frequently exposed to x-ray radiation may be at a higher risk for these skin cancers. Basil cell skin cancer rarely metastasizes; however, if left too long untreated, it may spread into surrounding tissue or even bone.

Another type of nonmelanoma skin cancer that is linked to UV radiation exposure is squamous cell carcinoma. In its earliest stages, squamous cell carcinoma is called Bowen's disease, or squamous cell in situ. In this stage, it has not yet spread to surrounding tissues. Actinic keratosis is a flaky, patchy, or warty skin lesion that can also lead to squamous cell carcinoma.

A squamous cell cancer may appear as a round, reddish patch—usually larger than 1 in. (2.5 cm) in diameter that is rough or scaly on the surface and that does not heal. Squamous cell cancers are more likely to occur in places where a person experiences sun exposure—such as the face, neck, arms, and hands—and on people who are fair-skinned, fair or red haired, blue or green eyed, and with a history of repeated sunburns early in life. They may also appear on people with a history of x-ray radiation exposure or who have had chemical exposures.

Melanoma is the most dangerous form of skin cancer and accounts for the leading cause of death among diseases of the skin. Melanomas are formed when changes occur to melanocytes—cells of the epidermis responsible for the production of melanin. Melanomas may occur in normal appearing skin, or in **moles** or other skin areas that have changed shape or appearance over time. More infrequently, melanomas can appear in the iris of the eye, the retina, or other areas inside the body. People most at risk for melanomas are the same individuals as those at risk for nonmelanomas, but all people can get this or other types of skin cancers.

Diagnosis

A visual inspection of the patient is performed by the medical professional, along with a historical review of the person's exposure to the sun and to artificial sunning devices (such as tanning beds). According to the Mayo Clinic, "If you experience sunburns or skin reactions after relatively minor exposures to sunlight, your doctor may recommend phototesting. During phototesting, small areas of your skin are exposed to measured amounts of UVA [those UV rays that have wavelengths from 400 to 315 nanometers)] and UVB

WWW.BOOKBAZ.IR

light to try to reproduce the problem. If your skin reacts to the UV radiation, you're considered sensitive to sunlight (photosensitive)."

Prevention

Whenever going out of doors, summer or winter, one should protect skin from ultraviolet radiation with the use of protective sunscreen of at least a factor of 15, although a sun protection factor (SPF) of 30 or above is recommended. When going out of doors, people should apply sunscreen liberally and often to all areas of the body, especially those areas that will be in direct sunlight. Protective sunglasses should be worn, those shades with UV filtering. Limiting the amount of time spent in sunlight and staying in the shade whenever possible are also helpful. Tanning beds should be avoided, as the ultraviolet radiation from the bulbs in these beds does contribute to skin damage such as burning, aging, and wrinkling, as well as all types of skin cancers.

Everyone from age six months on should use a water-resistant sunscreen with a sun protective factor (SPF) of at least 15. At least an ounce should be applied 15–30 minutes before going outside. It should be reapplied every two hours (more often after swimming). Babies should be kept completely out of the sun for the first six months of life, because their skin is thinner than older children. Sunscreens have not been approved for infants.

In addition, people should do the following:

- limit sun exposure to 15 minutes the first day, even if the weather is hazy, slowly increasing exposure daily
- reapply sunscreen every two hours (more often if sweating or swimming)
- reapply waterproof sunscreen after swimming more than 80 minutes, after toweling off, or after perspiring heavily
- avoid the sun between 10 A.M. and 3 P.M.
- use waterproof sunscreen on legs and feet, since the sun can burn even through water
- wear an opaque shirt in water, because reflected rays are intensified

Regarding a sunscreen under SPF 15, simply applying more of the same SPF will not prolong allowed time in the sun. Instead, individuals should use a higher SPF in order to lengthen exposure safely. A billed cap protects 70% of the face; however, a wide-brimmed hat is better. People at very high risk for skin cancer can wear clothing that blocks almost all UV rays, but most people can simply wear white cotton summer-weight clothing with a tight weave.

Treatment

Once sunburn has occurred, there is no treatment that can successfully remedy it, but there are measures that can be taken to help soothe the discomfort and help the healing process. Some of these measures are as follows:

- Cold compresses can be placed over the affected area or areas or people can take a cool bath.
- Moisturize applied such as aloe vera gel (best when cooled) or other moisturizers can soothe affected areas. Gels or creams with alcohol as an ingredient should be avoided, as alcohol will further dry out the skin.
- Pain reliever can be taken if necessary, such as an over-the-counter (OTC) non-steroidal anti-inflammatory drug (NSAID) like Advil or Motrin in cases where pain or fever persists.
- Calamine lotion can be applied as necessary.
- Dusting powder can be applied to reduce chafing.
- Colloidal oatmeal (Aveeno) baths can reduce irritation.

People who are severely sunburned should see a doctor, who may prescribe corticosteroid cream to speed healing.

It is important to remember that peeling skin may still be sensitive and to treat it gently. Attempting to rush the peeling process may cause tearing of new skin and may lead to infection. In addition, blisters should be left alone or covered in gauze. Attempting to break or squeeze blisters interferes with the body's natural healing process and may lead to infection.

Basil cell carcinomas are treated most frequently by types of surgical excision, or they may be frozen or irradiated. Squamous cell cancers are treated in the same manner as basil cell carcinomas; however, Bowen's disease—early stage squamous cells—may be treated with **photodynamic therapy**, wherein a combination of photosensitizing medication and **light therapy** is used to kill cancer cells.

Alternatives

Over-the-counter preparations containing aloe (*Aloe barbadensis*) are effective in treating sunburn and easing pain and inflammation while also relieving dryness of the skin. A variety of topical herbal remedies applied as lotions, poultices, or compresses may also help relieve the effects of sunburn. Calendula

(*Calendula officinalis*) is one of the most frequently recommended to reduce inflammation. Apple cider vinegar applied to the burn area also can help in relieving the pain of sunburns.

Prognosis

Moderately burned skin should heal within a week. Although the skin will heal after sunburn, the risk of skin cancer increases with exposure and subsequent burns. Even one bad burn in childhood carries an increased risk of skin cancer. Deaths have resulted from acute exposure from the Sun. More commonly; however, significant temporary disability often results in millions of people each year as they experience sunburn. Sometimes the skin does not burn but tans instead. In both cases, the skin has been damaged by an overexposure of UV rays. According to the U.S. National Institutes of Health, "There is no such thing as a 'healthy tan.' Unprotected sun exposure causes premature aging of the skin."

Precautions

People should avoid applying sunscreen to irritated skin. They should not use sunscreen on children younger than the age of six months unless a medical professional, such as a pediatrician, recommends doing so. Infants under the age of six years should avoid the sun and wear protective clothing whenever outside. Any child who develops serious sunburn should be taken for immediate medical help.

Using sunscreen is a good way to prevent sunburn in people of all ages, especially children. The sun protection factor (SPF) number on sunscreen products indicates how long the product should keep a person protected—although this time of protection varies among individuals. Generally, if a person begins to burn within 10 minutes after being out in the sun without the use of sunscreen, then a sunscreen with a SPF of 30 should protect for about 300 minutes. That is, the number of minutes it takes the skin to burn multiplied by the SPF number; in this case, 10 minutes times 30 equals 300 minutes. Sunscreen products should state that they block both UV-A and UV-B radiation.

If one burns easily then the person should reapply sunscreen more frequently than recommended. In addition, there are other ways to protect oneself from the harmful rays of the sun. Staying out of the sun during the hottest hours of the day is helpful. During these hours, one can prevent burning by staying in the shade. In addition, wearing adequate clothing helps one to avoid burning, such as a long-sleeved shirt, long pants, and a hat with a large bill or brim.

Sunscreen should be applied to the most vulnerable areas of the body, such as the back of the neck, nose, ears, and behind the knees. Making sure to cover all skin that will be exposed is necessary. The tops of feet are especially vulnerable.

Regarding buying sunscreen it is recommended to purchase products free of para-aminobenzoic acid (PABA) because the chemical can stain clothes and cause an allergic reaction in some individuals. Also sunscreens that contain retinyl palmitate (**vitamin A**) should be avoided because they may increase the risk of getting skin cancer when users exposed to sunlight. In addition, sunscreen and insect repellant should not be present in one product. Use two products for more effective results.

Risks

People with fair skin are at increased risk to sunburn than are people with dark skin. Darker skinned people have more melanin in their bodies, which offers some protection from sunburn but not from skin damage caused by UV rays. Dermatologists classify skin as to its degree of pigmentation, which is produced by melanocytes, or the pigment-producing cells of the body. Very little pigment is classified as type I, whereas very dark pigment is type VI, with four types in between:

- Type I: Pale white skin that always burns, never tans
- Type II: White skin that burns easily, tans minimally
- Type III: White skin that burns minimally, tans easily
- Type IV: Light brown or olive skin that burns minimally, tans easily
- Type V: Brown skin that rarely burns, tans easily and darkly
- Type VI: Dark brown or black skin that rarely burns, always tans, deeply pigmented

Aftercare

For most sunburn cases where a visit to a healthcare provider was necessary, individuals should follow up with a doctor, if so directed. After visiting a doctor for sunburn, if symptoms persist, individuals should contact the doctor if any of the following are present:

- fever
- red and itchy skin

Sunscreens

Definition

Sunscreens are products applied to the skin to protect against the harmful effects of the sun's ultraviolet (UV) rays, both UVA rays (those longer UV rays from 400 to 315 nanometers in length) and UVB rays (those shorter UV rays from 315 to 280 nanometers). The group of products called sunscreen is also called such names as sunblock, sun screen, and suntan lotion. Although suntan lotion is often used as a synonym for sunscreen, it does not provide protection against the damaging rays of the sun. Sunscreen is made primarily as a gel, lotion, and spray. The American Cancer Society recommends the regular use of sunscreen because it helps to prevent certain cancers such as squamous cell carcinomas and basal-cell carcinomas.

Description

Many brands of sunscreens are available, containing a variety of ingredients. The active ingredients work by absorbing, reflecting, or scattering some or all of the sun's rays. Most sunscreen products contain combinations of ingredients.

Sunscreens are usually grouped into two major categories, namely chemical absorbers and physical blockers. Chemical absorbers absorb high-intensity UV rays, whereas physical blockers reflect or scatter them. Chemical absorber compounds include avobenzone, padimate O, octyl methoxycinnamate, octisalate, and octocrylene. Physical blocker compounds include titanium dioxide and zinc oxide. The chief drawback of physical blockers is their tendency to leave a white film on the skin, causing many people to use less of the product than they should for full sun protection.

Sunscreen products are sold as lotions, creams, gels, oils, sprays, sticks, and lip balms and can be bought without a physician's prescription.

The U.S. Food and Drug Administration (FDA) has required sunscreen products to carry a sun protection factor (SPF) rating on their labels since 1999. This number tells the consumer how well the sunscreen protects against burning. The higher the number, the longer a person can stay in the Sun without burning. However, SPF ratings apply only to protection from UVB rays.

UVA rays damage the skin without burning. In the United States, the FDA has had in the past no mandatory criteria related to labeling of the effectiveness of sunscreens in blocking UVA rays. In fact, the United States and Canada do not require sunscreen companies to offer any UVA protection in their products. Thus, many sunscreens for sale in these two countries, even those specifically made for babies and children, offer little or no protection from UVA rays. Only sunscreen products that contain the ingredients zinc oxide, titanium dioxide, avobenzone, and mexoryl provide protection against UVA rays.

However, starting in January 2013, the FDA required substantiation of broad spectrum or UVA claims made by sunscreen-product companies. This substantiation means that any products that claim to provide UVA protection or to be a broad spectrum sunscreen must first pass a critical wavelength test. The test checks the wavelength at which the sunscreen allows 10% of the rays to penetrate. The FDA considers a sunscreen with a critical wavelength of over 370 nanometers to be one that provides excellent UVA protection from the sun.

Earlier, in October 2010, the FDA had proposed to require labeling of products with respect to their effectiveness in protecting against UVA rays, specifically with a one-to-four star rating system. A product with a one-star rating offered the lowest protection, whereas a four-star rating indicated the highest level of protection against UVA rays. Products that did not provide any protection against UVA rays would be labeled without a star and must state on the label "no UVA protection." The star rating was to be displayed near the SPF rating on the product label. This system was already in effect in the United Kingdom and Australia. However, the FDA decided not to implement a similar star-rating system and instead went with the critical wavelength test, which is a measure of the breadth of UVA protection.

Demographics

More than 2 million people in the United States are diagnosed with **skin cancer** each year. Skin cancer is the most common form of cancer in the country, but it is largely preventable through actions that protect the skin from the rays of the sun. The Environmental Protection Agency (EPA) estimates that approximately 65% of **melanoma** skin cancers and about 90% of nonmelanoma skin cancers are associated with exposure to UV radiation from the sun. Melanoma is a medical condition that causes a malignant tumor of melanocytes, which is responsible for skin color.

Purpose

Everyone needs a little sunshine. About 15 minutes of sun exposure each day helps the body make **vitamin D**, which is important for healthy bones and teeth. However, longer exposure may cause many problems, from wrinkles to skin cancer. One particularly deadly form of skin cancer, malignant melanoma, was on the rise between 1970 and 2010, as **tanning** (the process of browning of the skin after being exposed to the sun or an artificially made ultraviolet light source) became more popular. Over the same period, scientists warned that the thin layer of ozone that protects life on Earth from the sun's ultraviolet radiation is being depleted, which allows more UV radiation to get through, adding to the risk of overexposure.

Sunscreens help protect against the sun's damaging effects. The sun gives off two kinds of ultraviolet radiation—called UVA and UVB—that are able to

WWW.BOOKBAZ.IR

travel to the surface of Earth. Ultraviolet B (UVB) rays are thought to cause most basal cell and squamous cell skin cancers. Ultraviolet A (UVA) rays penetrate the skin more deeply than UVB rays which may lead to more skin damage.

Some medical experts are concerned that sunscreens give people a false sense of security, allowing them to stay in the sun longer than they should. Although sunscreens protect the skin from burning, they may not protect against other kinds of damage. A number of studies suggest that people who use sunscreens may actually increase their risk of melanoma because they spend too much time in the sun. This does not mean that people should stop using sunscreens. It means that they should not rely on sunscreens *alone* for protection. According to the American Academy of Dermatology, sunscreens should be one part of Sun protection, along with wide-brimmed hats and tightly woven clothing that covers the arms and legs.

Sunscreens are also recommended for patients with **rosacea** or other skin disorders that are aggravated by exposure to sunlight.

Precautions

Sunscreen alone will not provide full protection from the sun. When possible, one should wear a hat, long pants, a long-sleeved shirt, and sunglasses. Adults should consider dressing their children in protective clothing, designed to protect the child completely from the sun. They should also try to stay out of the sun between 10 A.M. and 2 P.M. Standard Time (11 A.M. to 3 P.M. Daylight Saving Time), when the sun's rays are strongest. The Shadow Rule should be followed: If one's shadow is shorter than one's body, the sun's UV rays are at their strongest and should be avoided. Seek out the shade during hours outside during the middle of the day.

The sun can damage the skin even on cloudy days, so using a sunscreen should be a habit every day. High elevations or areas with surfaces that reflect the sun's rays, such as beaches, water, concrete, or snow, should also be avoided.

Sunlamps, tanning beds, and tanning booths were once thought to be safer than the sun, because they give off mainly UVA rays. However, UVA rays are now known to cause serious skin damage, and exposure to UVA rays does increase the risk of developing melanoma. Health experts strongly advise people not to use these tanning devices. In fact, in 2009, the International Agency for Research on Cancer (IARC), which is a working group of the World Health Organization, stated that tanning beds and lamps are "especially hazardous to young people; those who use sunbeds before the age of 30 years increase their lifetime risk of melanoma, the deadliest form of skin cancer, by 75 percent."

People with fair skin, blond, red or light-brown hair, and blue or light-colored eyes are at greatest risk for developing skin cancer. So are people with many large skin **moles**. These people should avoid exposure to the sun as much as possible. However, even dark-skinned people, including African Americans and Hispanic Americans, may suffer skin damage from the sun and should be careful about exposure.

Other groups of people who should minimize sun exposure are those who have had organ transplants or recent **plastic surgery**. Patients who have received organ transplants have a greatly increased risk of developing skin cancer, and the facial skin of people who have had face lifts or similar plastic surgery procedures **sunburn** more easily than intact skin.

Sunscreens should not be used on infants under six months of age because of the risk of side effects. Instead, children this young should be kept out of the sun. Children over six months should be protected with clothing and sunscreens of at least SPF 15, preferably lotions. Sunscreens containing alcohol should not be used on children because they may irritate the skin.

Older people who stay out of the sun and use sunscreens may not produce enough vitamin D in their bodies. They may need to increase the vitamin D in their **diets** by including foods such as fortified milk and salmon. A healthcare professional can help determine if this precaution is necessary.

Anyone who has had unusual reactions to any sunscreen ingredients in the past should check with a physician or pharmacist before using a sunscreen. The physician or pharmacist should also be told about any **allergies** to foods, dyes, preservatives, or other substances, especially the following:

- artificial sweeteners
- anesthetics such as benzocaine, procaine, or tetracaine
- diabetes medicine taken by mouth
- hair dyes
- sulfa medicines
- water pills
- cinnamon flavoring

People with skin conditions or diseases should check with their physicians before using a sunscreen. This is especially true of people with conditions that get worse with exposure to light.

In addition, wearing sunglasses that protect the eyes and the skin surrounding the eyes from the ultraviolet rays of the sun is necessary.

Recommended dosage

One should be sure to read the instructions that come with a product. Some products need to be applied as long as one or two hours before Sun exposure. Others should be applied from 15 to 30 minutes before exposure and reapplied frequently during exposure.

People should apply sunscreen liberally to all exposed parts of the skin, including hands, feet, nose, ears, neck, scalp (if the hair is thin or very short), and eyelids. Users should take care not to get sunscreen in the eyes, as it can cause irritation. People should also use a lip balm containing sunscreen to protect the lips and reapply sunscreen liberally every one to two hours—more frequently when perspiring heavily or after swimming.

Generally, a sunscreen with a SPF of 15 filters out approximately 93% of all incoming UVB rays, whereas one with a SPF of 30 eliminates 97% and one with a SPF of 50 keeps out 98%.

Side effects

The most common side effects are drying or tightening of the skin. This problem does not need medical attention unless it does not improve. Other side effects are rare but possible. If any of the following symptoms occur, individuals should check with a physician as soon as possible:

- acne
- burning, itching, or stinging of the skin
- redness or swelling of the skin
- rash, with or without blisters that ooze and become crusted
- pain in hairy parts of body
- pus in hair follicles

Some side effects from sunscreens that are believed to be true by the public are considered false by the medical community. For one, using sunscreen will not cause a deficiency of vitamin D. Most dermatologists and all medical studies performed by researchers conclude that vitamin D deficiency does not occur with regular use of sunscreens. Another conclusion is that sunscreen should be used just as much on cold or cloudy days as it is on warm and clear days. Even when the sun is hidden behind clouds, up to 40% of the sun's UV rays still reach the surface of Earth. In addition, the sun's UV rays are still dangerous in cold weather as they are in warm weather. Finally, overexposure of UV rays is dangerous at any age, not just for babies and the very young. Preventing skin cancer with the use of sunscreens is important as one grows older, especially since people are living longer and spending more time outside.

Interactions

Anyone who is using a prescription or nonprescription (over-the-counter) drug that is applied to the skin should check with a physician before using a sunscreen.

Risks

The nonprofit organization Environmental Working Group (EWG) stated within its *Guide to Sunscreens* that only 25% of sunscreens in the U.S. market are "free of ingredients with serious safety concerns." The EWG also states that people should not be "fooled by high SPF" sunscreens. The organization states, "High-SPF products tempt people to apply too little sunscreen and stay in the sun too long. The FDA has proposed prohibiting the sale of sunscreens with SPF values greater than 50+, calling higher SPF values 'inherently misleading.'" But as of 2013 the FDA had not issued a regulation that carries the force of law.

The EWG also states that **vitamin A** added to sunscreen adds risk for added skin tumors and lesions. It states: "The sunscreen industry adds a form of vitamin A to nearly one-quarter of all sunscreens. Retinyl palmitate is an anti-oxidant that slows skin **aging**. However, federal studies indicate that it may speed the development of skin tumors and lesions when applied to skin in the presence of sunlight. EWG recommends that consumers avoid sunscreens, lip products, and skin lotions containing vitamin A, often labeled 'retinyl palmitate' or 'retinol.'."

The EWG also stated: "The ideal sunscreen would completely block UV rays that cause sunburn, immune suppression and damaging free radicals. It would remain effective on the skin for several hours. It would not form harmful ingredients when degraded by sunlight. It would smell and feel pleasant so that people would use more of it." However, the EWG stated that no sunscreen in the United States provides such protection. The organization stated that sunscreens made in Europe provide

Results

The June 4, 2012, *New York Times* article "Slathering on Sunscreen, Early and Often" makes the important point that sun exposure and its risks should be taken more seriously. If protection practices are instilled at an early age, then they become lifelong habits that can help protect an individual form sunburns, damage, and cancers.

Superior vena cava syndrome

Definition

The superior vena cava is the major vein in the chest that carries blood from the upper part of the body in to the heart. A restriction of the blood flow (occlusion) through this vein can cause superior vena cava syndrome (SVCS).

Description

Superior vena cava syndrome is a partial occlusion of the superior vena cava. This leads to a lower than normal blood flow through this major vein. SVCS is also called superior mediastinal syndrome and/or superior vena cava obstruction.

Causes and symptoms

More than 95% of all cases of SVCS are associated with cancers involving the upper chest. The cancers most commonly associated with SVCS are advanced lung cancers, which account for nearly 80% of all cases of SVCS, and lymphoma. Cancers that have spread (metastasized) to the chest, such as metastatic **breast cancer** to the chest and metastatic **testicular cancer** to the chest have also been shown to cause SVCS.

Other causes of SVCS include: the formation of a blood clot in the superior vena cava, enlargement of the thyroid gland, **tuberculosis**, and **sarcoidosis**.

The symptoms of SVCS include:

- change in voice
- confusion
- cough
- enlargement of the veins in the upper body, particularly those in the arms
- headache
- light-headedness
- shortness of breath
- swelling of the arms
- swelling of the face
- trouble swallowing

KEY TERMS

Metastasis—The spread of a cancer from one part of the body (where the cancer originated) to another part of the body.

Sarcoidosis—A disease of unknown origin in which there is chronic (recurrent) swelling in the lymph nodes and other tissues.

Superior vena cava—The major vein that carries blood from the upper body to the heart.

Thymoma—A tumor that originates in the thymus, a small gland just in front of the heart that produces hormones necessary for the development of certain components of the immune system.

Diagnosis

SVCS should be considered in any cancer patient with swelling of the face and arms. This diagnosis can be confirmed by x ray, computerized tomography (CT) scan, or medical resonance imaging (MRI) of the chest that reveals a partial occlusion of the superior vena cava.

Treatment

Treatment of SVCS depends on the underlying cancer that is causing it. This treatment may include radiation, **chemotherapy**, or a combination of both. In some cases, surgical procedures may be performed to open (dilate) the vessel. These procedures are generally performed by a trained radiologist or vascular surgeon.

Alternatives

Since treatment of SVCS is aimed at treating the underlying disorder that is causing SVCS, alternative treatments must also focus on treating these underlying causes. Alternative treatments for cancer include **acupuncture**, **aromatherapy**, herbal remedies, **hydrotherapy**, hypnosis, and massage, among many others.

WWW.BOOKBAZ.IR

Prognosis

The prognosis depends on the underlying cause of SVCS. In cases of SVCS caused by lung cancers, the prognosis is generally rather poor since SVCS does not generally occur until the later stages of these diseases.

Prevention

SVCS may be prevented by early medical intervention to halt and/or reverse the cancer which, in a later stage, would have lead to SVCS.

Surfactant

Definition

Surfactant is a complex naturally occurring substance made of six lipids (fats) and four proteins that is produced in the lungs. It can also be manufactured synthetically.

Purpose

Surfactant reduces the surface tension of fluid in the lungs and helps make the small air sacs in the lungs (alveoli) more stable. This keeps them from collapsing when an individual exhales. In preparation for breathing air, fetuses begin making surfactant while still in the womb. Babies that are born very prematurely often lack adequate surfactant and must receive surfactant replacement therapy immediately after birth in order to breathe.

Precautions

Babies are considered premature if they are born before 37 weeks gestation. Fetuses begin to produce surfactant between weeks 24 and 28. By about 35 weeks, most babies have enough naturally produced surfactant to keep the alveoli from collapsing. Babies born before 35 weeks, especially those born very prematurely (before 30 weeks), are likely to need surfactant replacement therapy. Over half the babies born before 28 weeks gestation need this treatment, while about one-third born between 32 and 36 weeks need supplemental surfactant. Some very premature infants may also need to be placed on a mechanical ventilator.

Description

The lungs consist of spongy tissue filled with air spaces called alveoli. In the alveoli, oxygen is taken up by the blood and carbon dioxide, a waste product of cellular metabolism, is released and exhaled. For efficient oxygen-carbon dioxide exchange to occur, the surface area of the alveoli must be as large as possible. Under normal conditions, when a person exhales, the alveoli would collapse into each other and form larger air sacs with less surface area. Surfactant prevents this collapse by reducing the surface tension of the fluids that line the lungs and helping to equalize the pressures between large and small air spaces.

Surface tension is a measure of the attraction molecules of a fluid have for each other. The attractive force pulls fluids into a shape with the smallest surface area. This is why a drop of water on a flat surface is rounded rather than flat. If the surface tension is lowered, the attraction among molecules of the fluid is decreased and the surface area of the fluid increases. For example, if a drop of detergent is added to a drop of water, the detergent reduces the surface tension and the drop of water flattens out.

In the lungs, surfactant reduces the surface tension and helps to maximize the surface area available for gas exchange. Without adequate surfactant, a baby works much harder to breathe, becomes exhausted, and does not get enough oxygen. Babies that do not have enough surfactant to breathe normally at birth are said to have infant **respiratory distress syndrome** (RDS) or hyaline membrane disease (HMD).

Babies with RDS are given replacement surfactant as soon as possible within the first six hours after birth. Manufactured surfactant is a white powder that is mixed with sterile water. It is given through a

breathing tube (endotracheal tube) that is inserted in the baby's lungs. Multiple doses are usually required.

Surfactant replacement therapy continues until the baby's lungs have matured enough to make surfactant on their own. Some very premature babies are also put on mechanical respirators to help them breathe. Surfactant replacement therapy has reduced deaths due to respiratory distress by 50% since the early 1990s. This therapy is expensive, but it is normally covered by insurance.

Preparation

The administration of surfactant is often a neonatal emergency. The only way to prevent the need for surfactant replacement therapy is to prevent a premature birth. Mothers who are at known high risk to deliver prematurely are given drugs called **corticosteroids** toward the end of the **pregnancy** that stimulate the lungs of the fetus to mature and begin producing surfactant sooner. This helps reduce the need for surfactant replacement therapy. Although babies of all races may be born prematurely, **prematurity** is more common if the mother is diabetic, is carrying multiple fetuses, or has delivered a previous premature baby. The decision to use surfactant replacement therapy is based on the condition of the baby, its blood oxygen level, and degree of respiratory distress.

Aftercare

Babies receiving surfactant therapy are normally cared for by a neonatologist, a pediatrician that specializes in newborn care. Premature newborns often have other health problems in addition to RDS. Aftercare varies depending on their other health risks.

Risks

Delivery of surfactant requires inserting a breathing tube into the baby's lungs. Complications of this therapy include air leaking into the area between the chest wall and the lungs and air leaking into the sac around the heart. Some infants also develop chronic lung disease.

Results

Normally surfactant replacement therapy keeps the infant alive until the lungs start producing their own surfactant.

KEY TERMS

Alveolus (plural alveoli)—The terminal air sacs of the lungs where gas exchange occurs.

Hyaline membrane—A thin layer of cells that line the lung.

Surface tension—The attraction of molecules in a fluid for each other.

Abnormal results

Surfactant replacement therapy is very effective if begun within six hours after birth. When it fails, death may result.

Swallowing disorders

Definition

Swallowing disorders include a number of diseases and conditions that cause difficulty in passing food or liquid from the mouth to the stomach.

Demographics

Each year, about 10 million people in the United States require medical evaluation for swallowing problems. Some experts say that about 10% of Americans develop symptoms of swallowing disorders in

WWW.BOOKBAZ.IR

adulthood. Elderly people are the most likely to have problems with swallowing.

Description

Although swallowing is normally automatic and unconscious on the part of an individual, it is a complex process involving several phases and 29 muscles. Saliva helps soften food as it is chewed. The tongue helps move food to the back of the mouth, triggering a swallowing reflex that passes food through the pharynx. The epiglottis helps keep food from mistakenly going down the windpipe and directs it instead into the esophagus, which is the canal that carries food to the stomach. Swallowing disorders can occur at any phase in the swallowing process. The medical term for difficulty swallowing is dysphagia.

Causes and symptoms

Swallowing disorders often result from other conditions and diseases. For example, Parkinson's disease, **cerebral palsy**, **stroke**, **head injury**, and other central nervous system conditions can damage the muscles and nerves involved in swallowing. Some people are born with abnormalities in the swallowing structures, such as infants born with **cleft palate**.

Some cancers can lead to swallowing disorders. **Esophageal cancer** can cause narrowing and eventual blockage of the esophagus. Surgery and **radiation therapy** for **head and neck cancer** can restrict or weaken tongue motion, paralyze vocal cords, or cause muscle damage that affects swallowing. An inflamed esophagus, often resulting from **gastroesophageal reflux disease** (GERD), can cause painful or difficulty swallowing. Infections of the esophagus also can inflame it and cause it to narrow. Swallowing difficulty may result from **aging**, although researchers are not certain why.

The most common symptoms people report are **choking** and the feeling that food feels stuck in the throat. Other symptoms include needing to swallow many times to clear food from the mouth and throat, a "gurgly" wet sound to the voice after swallowing, having to clear the throat after eating, coughing, **pain** while swallowing, bringing food back up (regurgitation), food or acid backing up into the throat, unexpected weight loss, and not being able to swallow at all. Children also may gag during meals and may have excessive drooling or leaking of food or liquid from their mouths during meals. They may have difficulty breathing when eating or drinking, spit up frequently, and lag behind in weight gain. They also may have recurring **pneumonia** or respiratory infections.

Diagnosis

A physician should perform a full head and neck examination based on the patient's symptoms. Speech-language pathologists may aid in the diagnosis. Physicians also might order a swallowing test to study how the patient swallows. The patient will be asked to drink a liquid with a contrast agent called barium that will show up on x rays of the throat and upper chest. The exam might be imaged with a technique called video fluoroscopy, which will take motion camera images in addition to still images. For this exam, the patient may be asked to swallow liquid, paste, and solids. A speech pathologist may work with the radiologist to perform this exam.

If the physician thinks the problem originates in the lower esophagus or has concerns about an abnormality in the esophagus, an **endoscopy** may be ordered. This test involves passing a thin, flexible instrument called an endoscope down the throat. The lighted endoscope helps the physician view the esophagus. Other tests may be used, including **ultrasound**.

Treatment

Treatment will depend on the cause of the swallowing problem. Special exercises may help strengthen the muscles used for chewing and swallowing. Problems originating in the mouth may be treated with artificial saliva, improved hydration, or better dental care. Esophageal problems will be treated depending on the cause. Patients with GERD will receive medications and instructions on how to better manage the disease. Esophageal cancer is a life-threatening disease that will involve coordinating care with an oncologist. Many patients will receive help with their disorders from speech pathologists. Special liquid **diets** may be ordered for patients who continue to have trouble chewing or swallowing. In severe cases, the patient may need a feeding tube that bypasses the part of the swallowing system that does not work.

Alternatives

Some herbs that may help improve swallowing include oil of peppermint and licorice. Valerian may be used as a tea. Homeopathic physicians may suggest some remedies aimed at improving bloating, **indigestion**, or **cough**. Alternative care should be sought from licensed practitioners and coordinated with physician care.

KEY TERMS

Cleft palate—An opening or hole in the roof of the mouth that occurs at birth when the roof fails to fully develop in the infant.

Epiglottis—A thin layer of cartilage behind the tongue that helps block food from entering the windpipe.

Pharynx—The muscular cavity that leads from the mouth and nasal passages to the larynx and esophagus.

Prognosis

In many cases, these disorders can be corrected. If not treated, swallowing disorders can lead to serious complications, including **dehydration** and **malnutrition**. There also is a risk of food entering the airway (aspiration) as a person attempts to swallow, which can lead to aspiration pneumonia as food particles enter the lungs.

Prevention

Many causes of swallowing disorders cannot be prevented. Slowly and fully chewing food helps. People with GERD should manage it to lower the risk of developing swallowing difficulties.

Sweat test

Definition

A sweat test, also known as a chloride sweat test, is used in the diagnosis of **cystic fibrosis** (CF), a genetic disease that affects the lungs and the digestive system. The test measures the level of salt excretions from the sweat glands. The level of salt provides a strong indicator of whether a patient has cystic fibrosis.

The sweat test is one of the most used and most reliable tests for the diagnosis of cystic fibrosis (CF), an incurable, inherited disease that affects the sweat glands, as well as glands in the lungs, intestines, bile duct, and pancreas. The test is administered as soon as CF is suspected, because early diagnosis and treatment can often ease the severity of the disease. CF may be suspected if the patient has a family history of the disease or if the patient is experiencing certain

WWW.BOOKBAZ.IR

symptoms, including slow development/growth, repeated lung infections, or certain digestive problems.

Sweat tests may be administered as early as the first week of life. However, this is recommended only when a family history of CF exists or symptoms specific to the disease are exhibited. Sweat tests should never be given for minor breathing problems. Because siblings of CF patients carry a 25% chance of having the disease, a diagnosis within a family should prompt the testing of brothers and sisters. For infants, the test is done on the thigh; for children and adults, the arm is used.

To conduct the test, an area of skin is first washed and dried, and then two metal electrodes are attached and fastened with straps. Two gauze pads are placed under the electrodes. One pad is soaked in salt water and the other in pilocarpine, which is a drug used to treat **dry mouth**. For a sweat test, pilocarpine is used to induce sweating. A tiny electric current is applied for five to ten minutes to carry the pilocarpine into the skin. The patient should only feel a slight tingling or tickling.

After the electrodes are removed, the skin is cleansed and dried again. A dry gauze pad, a piece of filter paper, or a plastic coil—known as a sweat patch—is taped or otherwise attached to the area where the pilocarpine was applied. The sweat patch is used to collect the sweat. After 30–45 minutes of collection time, the gauze, paper, or coil is placed in a sealed bottle and sent to a lab to be analyzed for salt—specifically chloride—content. In some cases, infants may not produce enough sweat for a reliable test, and therefore the test should be repeated. Results are typically available within a day, and sometimes before the patient goes home after the test.

Purpose

A sweat test is an indicator of CF. It is administered as soon as CF is suspected, either because of a family history or symptoms such as frequent colds, recurrent lung infections, recurrent **diarrhea**, difficulty absorbing food, and slower-than-normal growth.

Preparation

No preparation is necessary. Regular medications and diet may continue as normal. It is recommended that lotions or creams not be applied to the area to be tested for 24 hours prior to the test. Since the test can take an hour, parents of young children may want to bring books or toys to keep their children occupied during the test.

KEY TERMS

Cystic fibrosis—A life-threatening genetic disease that affects the lungs and the digestive system.

Pilocarpine—A drug used to treat dry mouth and glaucoma, also used to induce sweating in the sweat test that is used to help diagnose cystic fibrosis.

Aftercare

No aftercare is required. For some patients, the test area may be red and sweaty for several hours after the test, but this normalizes with time.

Results

For infants up to six months old, CF is very unlikely if chloride levels are 29 mmol/L or lower; CF is possible if levels are 30–59 mmol/L; and CF is likely if levels are 60 mmol/L or above. For older patients, CF is very unlikely if chloride levels are 39 mmol/L or lower; possible if levels are 40–59 mmol/L; and likely if levels are 60 mmol/L or above.

Risks

The test carries virtually no risks. No needles are used. The Cystic Fibrosis Foundation (CFF) recommends that sweat tests be performed at CFF-accredited care centers that adhere to strict guidelines and receive oversight to make sure the results are accurate.

Swollen glands

Definition

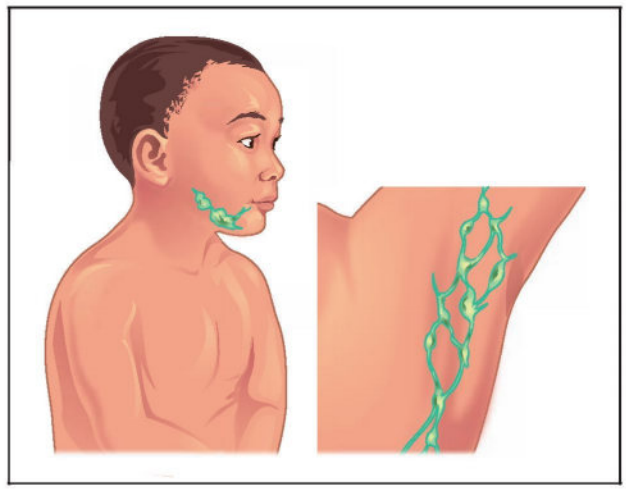
Swollen glands are enlarged lymph nodes. Lymph nodes are an integral part of the immune system and, although swollen glands can have many causes, they most often indicate that the body is fighting an infection. Swollen glands are also known as **lymphadenitis** or lymphadenopathy.

Demographics

Swollen glands are very common. They are one of the most frequent reasons for medical visits, especially by children. Swollen glands, especially in the neck region, are more common in children than in adults because children tend to have more viral infections than adults.

Description

Lymph glands or nodes are small, round or bean-shaped clusters of immune system cells called lymphocytes and macrophages. Lymphocytes are white blood cells that produce antibodies that recognize and bind to bacteria, viruses, and other foreign substances. Macrophages destroy these foreign invaders. There are about 600 lymph nodes located throughout the body, with the majority located in the head and neck region. Lymph glands occur in groups and filter the lymphatic fluid that drains from specific regions of the body, trapping and destroying bacteria, viruses, and other potentially harmful substances. They also help maintain the body's fluid balance.



Two common locations of swollen glands are in the neck and the armpit. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Lymph glands in children are normally about 0.4 in (1 cm) in diameter. They cannot be felt with the fingers unless they are swollen. The lymph glands that most often swell are those in the neck, under the jaw and chin, behind the ears, on the back of the head, and in the armpits and groin region. There are chains of lymph nodes on both sides of the front and back of the neck, as well as on each side of the neck. Swollen glands usually indicate that the numbers of lymphocytes in the glands have increased to produce more antibodies for fighting an infection.

Risk factors

Infection is the major risk factor for swollen glands. However, many other diseases and conditions can put a child at risk for swollen glands.

Causes and symptoms

There are numerous causes of swollen glands. An infection—especially a viral infection such as the common cold—is by far the most frequent cause. Infections that can cause swollen glands include:

- viral infections, such as flu, mononucleosis (mono), chicken pox, measles, rubella, mumps, and cytomegalovirus (CMV)
- bacterial infections, such as strep throat caused by the *Streptococcus pyogenes* bacterium, Lyme disease spread by ticks, tuberculosis (TB), and cat scratch fever

WWW.BOOKBAZ.IR

- viral and bacterial sexually transmitted infections (STIs), including syphilis
- parasitic infections such as toxoplasmosis
- mouth sores
- gingivitis, an infection of the gums
- an infected (abscessed or impacted) tooth
- skin infections
- ear infections
- tonsillitis
- infections from cuts, wounds, or animal or insect bites or stings
- a boil or abscess from an infected hair follicle or sweat gland

Other causes of swollen glands include:

- various cancers, especially leukemia, Hodgkin's disease, non-Hodgkin's lymphoma, and breast cancer
- cancers that have spread (metastasized) to lymph nodes
- immune system disorders, such as lupus, rheumatoid arthritis, and HIV/AIDS
- side effects of vaccines, such as immunizations against malaria or typhoid
- side effects of certain medications, such as phenytoin (Dilantin)

The location and type of infection or other condition determine which glands swell. Infections or tumors in the head, mouth, or neck are particularly likely to cause swollen glands:

- A sore throat often causes glands in the neck to swell.
- A tooth, gum, or other mouth infection may cause swollen glands in the jaw or neck.
- Swollen glands at the base of the neck and above the collarbone are indicative of a chest infection or, rarely, a tumor in the chest.
- An infection on the arm may cause glands in the armpit to swell.
- An infected animal bite can cause swollen glands above the wound.

Swollen glands that are soft, tender, and move easily are usually signs of infection or inflammation. Serious infections can cause swollen glands to become very hard and tender. Sudden, painful swelling is usually caused by an injury or early-stage infection. Swollen glands that are caused by cancer or a tumor tend to develop gradually and painlessly and remain swollen. They usually do not have other signs of inflammation, such as redness or tenderness. Swelling of glands throughout the body can be caused by a systemic infection, such as mononucleosis or HIV/AIDS, or an immune disorder, such as lupus or **rheumatoid arthritis**.

Swollen glands may be two or three times their normal size and can be readily felt with the fingers. Sometimes the swelling can be seen through the skin. A child's lymph node is considered to be enlarged if it is more than 0.4 in (1 cm) in diameter. Other symptoms of swollen glands include:

- a lump
- tenderness or pain when a gland is pressed
- red, warm, swollen skin over a lymph node
- symptoms of an underlying infection, such as fever, runny nose, mouth sores, or a sore throat
- a swollen limb, which can indicate an enlarged lymph node that is causing a blockage in the lymph system, but is too deep inside the body to feel through the skin

A child with swollen glands should be seen by a pediatrician if:

- the swelling and tenderness last for more than five days
- glands throughout the body appear swollen
- glands enlarge rapidly
- skin over a swollen gland turns red or purple
- the child has a fever above 101°F (38.3°C)
- the child is tired or lethargic or has no appetite

Diagnosis

Examination

During an examination, the healthcare provider feels all of the palpable lymph nodes—those that can be felt through the skin. The lymph glands are examined for size, texture, tenderness, warmth, and firmness. The location of the swollen glands may help diagnose the underlying cause. The **physical examination** includes any other symptoms that are present. Sometimes it is possible to see signs of infection or injury near the swollen gland. The healthcare provider will take a medical history that includes any exposure to infectious agents, recent injuries, and medications.

Tests

Infections may require growing (culturing) a sample of a bodily fluid or secretion to identify the causative agent and to select an appropriate antibiotic in the case of a bacterial infection. Sometimes an infected lymph node is drained and cultured. A **tuberculosis** skin test or specific tests to diagnose mononucleosis may be required.

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein called an antigen.

Lymph nodes—Lymph glands; small, round or pea-shaped tissue masses that are distributed along the lymphatic vessels and contain lymphocytes that filter the lymphatic fluid.

Lymphatic system—Consists of lymphatic fluid and vessels, lymph nodes, lymphocytes, and the thymus, spleen, tonsils, and bone marrow. The part of the circulatory system that is responsible for immune responses, that scavenges fluids and proteins and returns them to the blood, and that removes debris and foreign substances.

Lymphocyte—A type of white blood cell that functions in the immune response, including antibody-producing B cells and T cells.

Macrophage—A type of immune system cell that engulfs and destroys antigens and presents them to other immune system cells.

Blood tests to help diagnose the underlying cause of swollen glands may include:

- a complete blood count (CBC)
- a blood differential, which measures the percentages of each type of white blood cell
- liver function tests
- kidney function tests

Procedures

Procedures for diagnosing the underlying cause of swollen glands may include a:

- chest x ray
- liver-spleen scan
- computerized tomography (CT) scan of the affected area

Sometimes a **lymph node biopsy** is necessary for diagnosis, especially for diagnosis of a tumor or a fungal infection. A fine-needle aspiration (FNA), in which a thin, hollow needle is inserted into the node to remove or aspirate cells, may be performed in the physician's office or by a surgeon or radiologist. **Ultrasound** may be used to guide the needle. A surgical biopsy removes some or all of a lymph node through an incision and is performed under local or general **anesthesia**. The cells or tissue are sent to a laboratory for examination under a microscope.

Treatment

Swollen glands most often return to normal on their own once the underlying infection is resolved. Likewise, swollen glands caused by a **vaccination** usually resolve on their own. Swelling caused by a medication may require changing the dose or type of drug. If the gland itself is infected, surgical drainage may be required. Swollen glands caused by an underlying condition such as cancer or an immune system disorder require treatment of the underlying disease.

Drugs

Swollen glands can be treated with over-the-counter **pain** relievers, such as **acetaminophen** (Tylenol) or a nonsteroidal anti-inflammatory drug (NSAID), such as ibuprofen (Advil, Motrin) or naproxen (Aleve). Children should not be given **aspirin** without consulting a physician, due to the unlikely but serious risk of developing Reye's syndrome. Swollen glands caused by a bacterial infection are usually treated with **antibiotics**.

Alternatives

As with traditional treatments, alternative treatments for swollen glands depend on the cause. For example, many alternative practitioners recommend vitamin C and zinc or herbal remedies, such as *Echinacea* spp., for treating common colds.

Home remedies

A tender or painful swollen gland can be treated with warm, wet compresses. A washcloth wrung out with warm water should be applied for 20–30 minutes, three or four times per day. The heat and moisture can relieve discomfort, increase circulation to the area, localize the infection, and encourage healing. If possible, the gland should be exposed to the air. Swollen glands should not be rubbed, squeezed, scratched, or otherwise irritated. Bed rest also can be helpful for treating swollen glands.

Prognosis

Swollen glands are rarely serious. Soreness in swollen glands usually disappears within a couple of days without treatment. Swollen glands often return to their normal size as soon as an infection, such as a cold, has resolved. However, it may be several weeks after an infection has cleared before the glands return to their normal size. When swollen glands result from a serious infection or other underlying condition, they may remain enlarged for a long period.

WWW.BOOKBAZ.IR

Prevention

Although there are no specific preventative measures for the less frequent causes of swollen glands, there are measures that can help prevent swollen glands caused by infection. Frequent and thorough hand washing, especially during cold and flu season, is one of the best ways to prevent infection. Proper cleaning of **wounds** and prompt treatment with antibiotics, if required, can prevent swollen glands. Measures for preventing skin infections include:

- keeping the skin clean with mild soap or cleanser and lukewarm water
- rinsing thoroughly and gently patting the skin dry after washing
- avoiding irritating skin products
- using water-based and oil-free or hypoallergenic skincare products that do not clog pores
- washing as soon as possible after sweating
- wearing soft, cotton clothing or moleskin under sports equipment to avoid irritation
- avoiding squeezing, scratching, draining, or puncturing swollen glands, so as not to inflame or irritate the glands or push infection deeper into the skin

Sydenham's chorea

Definition

Sydenham's chorea is an acute but self-limited movement disorder that occurs most commonly in children between the ages of 5 and 15 and occasionally in pregnant women. It is closely associated with **rheumatic fever** following a throat infection. The disorder is named for Thomas Sydenham (1624–1689), an English doctor who first described it in 1686. Other names for Sydenham's chorea include simple chorea, chorea minor, acute chorea, rheumatic chorea, juvenile chorea, and St. Vitus' dance. The English word *chorea* itself comes from the Greek word *choreia*, which means "dance." The disorder takes its name from the rapid involuntary jerking or twitching movements of the patient's face, limbs, and upper body.

Description

Sydenham's chorea is a disorder that occurs in children and is associated with rheumatic **fever**. Rheumatic fever is an acute **infectious disease** caused by certain types of streptococci bacteria. It usually starts with **strep throat** or **tonsillitis**. These types of streptococci are able to cause disease throughout the body. The most serious damage caused by rheumatic fever is to the valves in the heart. At one time, rheumatic fever was the most common cause of damaged heart valves, and it still is in most developing countries around the world. Rheumatic fever and rheumatic **heart disease** are still present in the industrialized countries, but the incidence has dropped substantially.

Both acute rheumatic fever and Sydenham's chorea are relatively uncommon disorders in the United States. According to the Centers for Disease Control and Prevention (CDC), only 1–3% of people with streptococcal throat infections develop acute rheumatic fever (ARF); thus the incidence of ARF in

the United States is thought to be about 0.5 per 100,000 patients between 5 and 17 years of age.

With regard to age, the incidence of Sydenham's chorea is higher in childhood and adolescence than in adult life. It occurs more frequently in females than in males; the gender ratio is thought to be about 2 F: 1 M. Since the peak incidence of rheumatic fever in North America occurs in late winter and spring, Sydenham's chorea is more likely to occur in the summer and early fall. There is no evidence that the disorder selectively affects specific racial or ethnic groups.

Rheumatic fever may appear in several different forms. Sydenham's chorea is one of five major criteria for the diagnosis of rheumatic fever. There are also four minor criteria and two types of laboratory tests associated with the disease. The "Jones criteria" define the diagnosis. They require laboratory evidence of a streptococcal infection plus two or more of the criteria. The laboratory evidence may be identification of streptococci from a **sore throat** or antibodies to streptococcus in the blood. The most common criteria are arthritis and heart disease, occurring in half to three-quarters of the patients. Sydenham's chorea, characteristic nodules under the skin, and a specific type of skin rash occur only 10% of the time.

About 20% of patients diagnosed with Sydenham's chorea experience a recurrence of the disorder, usually within two years of the first episode. Most women who develop Sydenham's during **pregnancy** have a history of acute rheumatic fever in childhood or of using birth control pills containing estrogen.

Causes and symptoms

Sydenham's is caused by certain types of streptococci called Group A beta-hemolytic streptococci or GAS bacteria. In general, streptococci are spherical-shaped anaerobic bacteria that occur in pairs or chains. GAS bacteria belong to a subcategory known as pyogenic streptococci, which means that the infections they cause produce pus. These particular germs seem to be able to create an immune response that attacks the body's own tissues along with the germs. Those tissues are joints, heart valves, skin, and brain.

The initial throat infection that leads to Sydenham's chorea is typically followed by a symptom-free period of 1–5 weeks. The patient then develops an acute case of rheumatic fever (ARF), an inflammatory disease that affects multiple organ systems and tissues of the body. In most patients, ARF is characterized by fever, arthritis in one or more joints, and carditis, or inflammation of the heart. In about 20% of patients, however, Sydenham's chorea is the only indication of ARF. Sydenham's is considered a delayed complication of rheumatic fever; it may begin as late as 12 months after the initial sore throat, and it may start only after the patient's temperature and other physical signs have returned to normal. The average time interval between the pharyngitis and the first symptoms of Sydenham's, however, is eight or nine weeks.

It is difficult to describe a "typical" case of Sydenham's chorea because the symptoms vary in speed of onset as well as severity. Most patients have an acute onset of the disorder, but in others, the onset is insidious, which means that the symptoms develop slowly and gradually. In some cases, the child's physical symptoms are present for 4–5 weeks before they become severe enough for the parents to consult a doctor. In other cases, emotional or psychiatric symptoms precede the clumsiness and involuntary muscular movements that characterize the disorder. The psychiatric symptoms that may develop in patients with Sydenham's chorea are one reason why it is sometimes categorized as a PANDAS disorder. PANDAS stands for Pediatric Autoimmune Neuropsychiatric Disorders Associated with **Streptococcal Infections**.

Behavioral or emotional disturbances that have been observed with Sydenham's include:

- frequent mood changes
- episodes of uncontrollable crying
- behavioral regression; that is, acting like much younger children
- mental confusion
- general irritability
- difficulty concentrating
- impulsive behavior

Some researchers think that children who have had Sydenham's are at increased risk of developing **obsessive-compulsive disorder** (OCD). OCD is characterized by obsessions, which are unwanted recurrent thoughts, images, or impulses, and by compulsions, which are repetitive rituals, mental acts, or behaviors. Obsessions in children often take the form of fears of intruders or harm coming to a family member. Compulsions may include such acts as counting silently, washing the hands over and over, insisting on keeping items in a specific order, checking repeatedly to make sure a door is locked, and similar behaviors.

KEY TERMS

Arthralgia—Joint pain.

Chorea—Refers to rapid, jerky, involuntary movements of the limbs or face that characterize several different disorders of the nervous system, including chorea of pregnancy and Huntington's chorea as well as Sydenham's chorea.

Electrocardiogram—A map of the electrical activity of the heart.

Insidious—Developing in a stealthy or gradual manner. Sydenham's chorea may have an insidious onset.

PANDAS disorders—A group of childhood disorders associated with such streptococcal infections as scarlet fever and "strep throat." The acronym stands for Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections. Sydenham's chorea is considered a PANDAS disorder.

Pharyngitis—Inflammation of the throat, accompanied by dryness and pain. Pharyngitis caused by a streptococcal infection is the usual trigger of Sydenham's chorea.

Rheumatic fever—Chiefly childhood disease marked by fever, inflammation, joint pain, and Syndenham's chorea. It is often recurrent and can lead to heart valve damage.

St. Vitus' dance—Another name for Sydenham's chorea. St. Vitus was a fourth-century martyr who became the patron saint of dancers and actors during the Middle Ages. He was also invoked for protection against nervous disorders, epilepsy, and the disease that bears his name.

Streptococcus (plural, streptococci)—A genus of spherical-shaped anaerobic bacteria occurring in pairs or chains. Sydenham's chorea is considered a complication of a streptococcal throat infection.

Tonsillitis—Inflammation of the tonsils, which are in the back of the throat.

Diagnosis

Because rheumatic fever is such a damaging disease, a complete evaluation should be done whenever it is suspected. This includes cultures for streptococci, blood tests, and usually an electrocardiogram (heartbeat mapping to detect abnormalities).

The diagnosis of Sydenham's is also based on the doctor's observation of the patient's involuntary movements. Unlike tics, the movements associated with chorea are not repetitive; and unlike the behavior of hyperactive children, the movements are not intentional. The recent onset of the movements rules out a diagnosis of **cerebral palsy**. If doctors suspect Sydenham's, they may ask their patients to stick out their tongue and keep it in that position or to squeeze the doctor's hand. Many patients with Sydenham's cannot hold their mouth open and keep the tongue out for more than a second or two. Another characteristic of Sydenham's is an inability to grip with a steady pressure; when the patient squeezes the doctor's hand, the strength of the grip will increase and decrease in an erratic fashion. This characteristic is sometimes called the "milking sign."

Treatment

Suspected streptococcal infections must be treated. All the other manifestations of rheumatic fever, including Sydenham's chorea and excluding heart valve damage, remit with the acute disease and do not require treatment. Sydenham's chorea generally lasts for several months.

Most patients with Sydenham's chorea recover after a period of bed rest and temporary limitation of normal activities. In most cases the symptoms disappear gradually rather than stopping abruptly.

Most doctors recommend ongoing treatment with penicillin to prevent a recurrence of rheumatic fever or Sydenham's chorea, although there is some disagreement as to whether this treatment should continue for 5 years after an acute attack or for the rest of the patient's life. The penicillin may be given orally or by injection. Patients who cannot take penicillin may be given erythromycin or sulfadiazine.

Prognosis

Syndenham's chorea usually clears up without complications when the rheumatic fever is treated. The heart valve damage associated with rheumatic fever may lead to heart trouble and require a surgical valve repair or replacement.

In most cases of Sydenham's, the patient recovers completely, although a recurrence is possible. In a very few cases—about 1.5% of patients diagnosed with Sydenham's—there may be increasing muscle stiffness

and loss of muscle tone resulting in disability. This condition is occasionally referred to as paralytic chorea

Prevention

All cases of strep throat in children should be treated with a full 10 days of **antibiotics** (penicillin or erythromycin). Treatment may best be delayed a day or two to allow the body to build up its own antibodies. In addition, for those who have had an episode of rheumatic fever or have damaged heart valves from any other cause, prophylactic antibiotics should be continued to prevent recurrence.

It is possible to eradicate dangerous GAS bacteria from a community by culturing everyone's throat and treating everyone who tests positive. This is worth doing wherever a case of rheumatic fever appears, but it is expensive and requires many resources.

Sympathectomy

Definition

Sympathectomy is a surgical procedure that destroys nerves in the sympathetic nervous system. The procedure is performed to increase blood flow and decrease long-term **pain** in certain diseases that cause narrowed blood vessels. It can also be used to decrease excessive sweating. This surgical procedure cuts or destroys the sympathetic ganglia, which are collections of nerve cell bodies in clusters along the thoracic or lumbar spinal cord.

Purpose

The autonomic nervous system controls involuntary body functions such as breathing, sweating, and blood pressure. It is subdivided into two components, the sympathetic and the parasympathetic nervous systems.

The sympathetic nervous system speeds the heart rate, narrows (constricts) blood vessels, and raises blood pressure. Blood pressure is controlled by means of nerve cells that run through sheaths around the arteries. The sympathetic nervous system can be described as the "fight or flight" system because it allows humans to respond to danger by fighting off an attacker or running away. When danger threatens, the sympathetic nervous system increases heart and respiratory rates and blood flow to muscles, and decreases blood flow to other areas such as skin, digestive tract, and limb veins. The net effect is an increase in blood pressure.

Sympathectomy is performed to relieve intermittent constricting of blood vessels (ischemia) when the fingers, toes, ears, or nose are exposed to cold (Raynaud's phenomenon). In Raynaud's phenomenon, the

KEY TERMS

Causalgia—A severe burning sensation sometimes accompanied by redness and inflammation of the skin. Causalgia is caused by injury to a nerve outside the spinal cord.

Claudication—Cramping or pain in a leg caused by poor blood circulation, frequently caused by hardening of the arteries (atherosclerosis). Intermittent claudication occurs only at certain times, usually after exercise, and is relieved by rest.

Fiberoptics—In medicine, use of glass or plastic fibers to transmit light through a specially designed tube inserted into organs or body cavities where it transmits a magnified image of the internal body structures.

Hyperhidrosis—Excessive sweating. Hyperhidrosis can be caused by heat, overactive thyroid glands, strong emotion, menopause, or infection.

Parasympathetic nervous system—The division of the autonomic (involuntary) nervous system that slows heart rate, increases digestive and glandular activity, and relaxes the sphincter muscles that close off body organs.

Percutaneous—Performed through the skin. It is derived from two Latin words, *per* (through) and *cutis* (skin).

Pneumothorax—A collection of air or gas in the chest cavity that causes a lung to collapse. Pneumothorax may be caused by an open chest wound that admits air.

affected extremities turn white, then blue, and red as the blood supply is cut off. The color changes are accompanied by numbness, tingling, burning, and pain. Normal color and feeling are restored when heat is applied. The condition sometimes occurs without direct cause but is more often caused by an underlying medical condition, such as **rheumatoid arthritis**. Sympathectomy is usually less effective when Raynaud's syndrome is caused by an underlying medical condition. Narrowed blood vessels in the legs that cause painful cramping (claudication) are also treated with sympathectomy.

Sympathectomy may be helpful in treating **reflex sympathetic dystrophy** (RSD), a condition that sometimes develops after injury. In RSD, the affected limb is painful (causalgia) and swollen. The color, temperature, and texture of the skin changes. These symptoms are related to prolonged and excessive sympathetic nervous system activity.

Sympathectomy is also effective in treating excessive sweating (**hyperhidrosis**) of the palms, armpits, or face.

Demographics

Experts estimate that 10,000–20,000 sympathectomy procedures are performed each year in the United States.

Description

A sympathectomy is usually performed by a general surgeon, neurosurgeon, or surgeon with specialty training in head and neck surgery.

Sympathectomy was traditionally performed on an inpatient under general **anesthesia**. An incision was made on the mid-back, exposing the ganglia to be cut. Recent techniques are less invasive. As a result, the procedure may be performed under local anesthesia in an outpatient surgical facility.

Sympathectomy for hyperhidrosis is accomplished by making a small incision under the armpit and introducing air into the chest cavity. The surgeon inserts a fiberoptic tube (endoscope) that projects an image of the operation on a video screen. The ganglia are cut with fine scissors attached to the endoscope. Laser beams may also be used to destroy the ganglia.

If only one arm or leg is affected, it may be treated with a percutaneous radiofrequency technique. In this technique, the surgeon locates the ganglia by a combination of x-ray and electrical stimulation. The ganglia are destroyed by applying radio waves through electrodes on the skin.

Diagnosis

A reversible block of the affected nerve cell (**ganglion**) determines if sympathectomy is needed. This procedure interrupts nerve impulses by injecting the ganglion with a steroid and anesthetic. If the block has a positive effect on pain and blood flow in the affected area, the sympathectomy will probably be helpful. The surgical procedure should be performed only if conservative treatment has not been effective. Conservative treatment includes avoiding exposure to **stress** and cold, and the use of **physical therapy** and medications.

Sympathectomy is most likely to be effective in relieving reflex sympathetic dystrophy if it is performed

soon after the injury occurs. The increased benefit of early surgery must be balanced against the time needed to promote spontaneous recovery and responses to more conservative treatments.

Preparation

Patients should discuss expected results and possible risks with their surgeons. They should inform their surgeons of all medications they are taking, and provide a complete medical history. Candidates for surgery should have good general health. To improve general health, a surgical candidate may be asked to lose weight, give up **smoking** or alcohol, and get the proper amount of sleep and **exercise**. Immediately before the surgery, patients will not be permitted to eat or drink, and the surgical site will be cleaned and scrubbed.

Aftercare

The surgeon informs the patient about specific aftercare needed for the technique used. **Doppler ultrasonography**, a test using sound waves to measure blood flow, can help to determine whether sympathectomy has had a positive result.

The operative site must be kept clean until the incision closes.

Risks

Side effects of sympathectomy may include decreased blood pressure while standing, which may cause **fainting**. After sympathectomy in men, semen is sometimes ejaculated into the bladder, possibly impairing fertility. After a sympathectomy is performed by inserting an endoscope in the chest cavity, some persons may experience chest pain with deep breathing. This problem usually disappears within two weeks. They may also experience pneumothorax (air in the chest cavity).

Results

Studies show that sympathectomy relieves hyperhidrosis in more than 90% of cases and causalgia in up to 75% of cases. The less invasive procedures cause very little scarring. Most persons stay in the hospital for less than one day and return to work within a week.

Morbidity and mortality rates

In 30% of cases, surgery for hyperhidrosis may cause increased sweating on the chest. In 2% of cases, the surgery may cause increased sweating in other areas, including increased facial sweating while eating. Less frequent complications include Horner's syndrome, a condition of the nervous system that causes the pupil of the eye to close, the eyelid to droop, and sweating to decrease on one side of the face. Other rare complications are nasal blockage and pain to the nerves supplying the skin between the ribs. Mortality is extremely rare, and usually attributable to low blood pressure.

Alternatives

Nonsurgical treatments include physical therapy, medications, and avoidance of stress and cold. These measures reduce or remove the likelihood of triggering a problem mediated by the sympathetic nervous system.

Syphilis

Definition

Syphilis is a sexually transmitted disease (STD) caused by the spirochete bacterium *Treponema pallidum*. The infection is acquired through direct—usually sexual—contact with a syphilis sore. It also can be transmitted from a mother to her child either before or during birth. Untreated syphilis is a systemic, potentially fatal disease that can cause permanent damage to the heart and central nervous system.

Demographics

Syphilis has been a serious **public health** problem since at least the sixteenth century. Some estimates place the number of worldwide syphilis cases at about 50 million annually. However the incidence of syphilis varies greatly from one region to another and even within small geographical areas.

There were almost 49,903 new cases of syphilis reported in the United States in 2011-2012. This included 15,667 cases of primary and secondary syphilis, 14,503 cases of early-latent syphilis, 19,411 cases of late-latent syphilis, and 322 cases of congenital syphilis in newborns. These numbers represent a significant increase from those reported in 2000. In 2012 the rate of syphilis in the United States was 5 per 100,000 people, compared with 447 per 100,000 in 1943. The South accounts for 43.5% of all syphilis cases in the United States and only a small number of counties and urban areas account for the vast majority of cases.

This patient has secondary syphilis, evidenced by the appearance of lesions on the skin. *(Custom Medical Stock Photo, Inc.)*

In the United States syphilis primarily affects people aged 20–29. The highest numbers of cases are in women aged 20–24 and in men aged 20–29. Syphilis rates are highest among black Americans. In 2007 males accounted for six times the number of new syphilis cases as females. Men who have sex with men (MSM) account for more than 75% of cases reported in 2012. The increase in syphilis cases attributable to MSM increased from 7% in 2000 to 64% in 2004. Syphilis has been closely associated with HIV infection since the late 1980s. Syphilis makes it easier to transmit and acquire HIV. The incidence of syphilis is also high among crack cocaine users.

Description

Although the origin of syphilis remains controversial, evidence suggests that *Treponema* bacteria were brought to Europe from the New World with the return of Christopher Columbus's ships. Syphilis,

which is also called lues from a Latin word meaning plague, was treated with mercury and other dangerous substances until World War I, when more effective treatments based on arsenic or bismuth were introduced. After World War II penicillin became available to cure syphilis and the incidence of the disease began to decline.

About 90% of syphilis cases are contracted through sexual contact, usually from people who are unaware that they have the disease. Syphilis is sometimes called the "great imposter," because its symptoms—when present at all—resemble those of various other diseases.

Syphilis is transmitted through direct contact with a syphilis sore, usually through vaginal, anal, or oral sex. Sores usually occur on the external genitals or in the vagina, anus, or rectum, but also can occur on the lips and in the mouth. The chances of contracting syphilis during unprotected sex with a person who has an early stage of the disease are 30–50%. The bacteria also can be transmitted by touching infected sores or using contaminated needles to inject drugs. Babies of infected mothers can be born with congenital syphilis. Transmission through a blood **transfusion** is very rare because the bacterium cannot survive for more than 24 hours in stored blood and blood products are screened for the bacteria. Syphilis cannot be spread through toilet seats, doorknobs, swimming pools, hot tubs, bathtubs, shared clothing, or eating utensils. *T. pallidum* is easily killed by heat and drying.

Syphilis has both acute and chronic phases that produce a wide variety of symptoms affecting most of the body's organ systems. The range of symptoms makes it easy to ignore early signs or to confuse it with less serious diseases. Syphilis that is acquired through sexual contact has four stages—primary, secondary, latent, and tertiary. The bacteria can be spread by sexual contact during the first three stages. Although latent syphilis has few external symptoms, the disease continues to progress. Patients with tertiary syphilis cannot infect others.

Syphilis can be transmitted from an infected mother to her fetus through the placenta at any time during **pregnancy** or through contact with syphilitic **ulcers** during the birth process. The chances of infection depend on the stage of the mother's disease. Almost all infants born to mothers with untreated primary or secondary syphilis are infected. If a woman has untreated syphilis acquired within four years of a pregnancy, there is an 80% risk that the newborn will have congenital syphilis. However the infection rate drops to 40% if the mother's disease is in the early-latent stage and to 6–14% if she has late-latent syphilis.

Untreated syphilis can have devastating consequences:

- Syphilis appears to increase a man's risk of developing prostate cancer in later life.
- Cardiovascular syphilis occurs in 10–15% of patients with tertiary syphilis.
- About 8% of those with untreated syphilis develop neurosyphilis 5–35 years after the onset of the primary infection. This central nervous system disease has both physical and psychiatric consequences. It affects men more frequently than women and Caucasians more frequently than blacks.
- General paresis, also called dementia paralytica, results from neurosyphilis and is most common in patients over age 40.

Risk factors

In the United States and Canada, populations at high risk for syphilis include:

- sexually abused children
- sexually active teenagers
- MSM
- women of childbearing age
- prisoners
- abusers of drugs or alcohol
- prostitutes of either sex and their customers
- those infected with another sexually transmitted infection (STI), including HIV/AIDS

Drug abuse can increase the risk of syphilis because of needle sharing and the exchange of sex for drugs. In addition, people abusing drugs or alcohol are more likely to engage in risky sexual practices.

Causes and symptoms

T. pallidum is a thin, spiral- or coil-shaped bacterium that enters the body through mucous membranes or breaks in the skin to cause primary syphilis. The first signs of infection often go unnoticed. After an incubation period of 10–90 days chancres may develop. These are small blister-like sores about 0.5 in (13 mm) in size. They resemble the ulcers of chlamydia infection, **genital herpes**, or skin tumors. Most chancres are on the genitals, but they also can develop on the breasts or lips or in the mouth. Rectal chancres are common in MSM. Chancres in a woman's vagina or on her cervix are easily overlooked. Chancres are not painful and

WWW.BOOKBAZ.IR

disappear in three to six weeks without treatment. About 70% of patients with primary syphilis develop swollen lymph nodes near the chancre. The nodes may feel firm or rubbery but are not usually painful.

The disease continues to progress even in the complete absence of symptoms. Secondary syphilis begins between six weeks and six months after infection. Chancres may still be present but are usually healing. Secondary syphilis is a systemic infection marked by the eruption of skin **rashes** and ulcers in the mucous membranes. The skin rash may resemble other skin disorders such as drug reactions, **rubella**, **ringworm**, mononucleosis, or **pityriasis rosea**. Characteristics of a syphilis rash include:

- coppery color
- absence of pain or itching
- occurrence on the palms of the hands and soles of the feet

The skin eruptions may resolve in a few weeks or last as long as a year. Some patients develop condylomata lata—weepy, pinkish or grey patches of flattened skin on moist areas of the body. The skin rashes, mouth and genital ulcers, and condylomata lata are all highly contagious.

About 50% of patients with secondary syphilis develop swollen lymph nodes in the armpits, groin, and neck; about 10% develop inflammations of the eyes, kidney, liver, spleen, bones, joints, or the meninges—membranes covering the brain and spinal cord. Patients also may have flu-like symptoms, including low **fever**, chills, loss of appetite, **headache**, runny nose, **sore throat**, and aching joints.

The latent phase of syphilis is divided into early latency, occurring less than two years after infection, and late latency. During early latency patients are at risk for spontaneous recurrences of the ulcers and skin rashes of secondary syphilis. In late latency these recurrences are much less common. Late latency can either resolve spontaneously or continue for the remainder of the patient's life.

About 35–40% of untreated syphilis cases progress to the tertiary stage. Tertiary syphilis can be either benign late syphilis or cardiovascular and/or neurosyphilis.

Benign late syphilis begins three to ten years after infection and is characterized by the development of gummas. These are rubbery tumor-like growths that usually involve the skin or long bones, but also can develop in the eyes, mucous membranes, throat, liver, or stomach lining. Gummas have become uncommon since the introduction of **antibiotics** for treating syphilis. Benign late syphilis is usually rapid in onset and responds well to treatment.

Cardiovascular syphilis develops between 10 and 25 years after infection and often occurs along with neurosyphilis. It usually begins as an inflammation of the arteries leading from the heart and causes heart attacks, scarring of the aortic valves, **congestive heart failure**, or an **aortic aneurysm**.

There are four types of neurosyphilis:

- Asymptomatic neurosyphilis causes no central nervous system symptoms but can be detected in the spinal fluid.
- Meningovascular neurosyphilis is characterized by changes in the blood vessels of the brain or inflammation of the meninges. It causes headaches, irritability, and visual problems. If the spinal cord is involved, the patient may experience weakness of the shoulder and upper arm muscles.
- Tabes dorsalis is a progressive degeneration of the spinal cord and nerve roots, causing a loss of perception of body position and orientation in space and resulting in loss of muscle reflexes and difficulty walking. Patients may have shooting pains in the legs and periodic episodes of pain in the abdomen, throat, bladder, or rectum. Tabes dorsalis is sometimes called locomotor ataxia.
- General paresis affects the cortex of the brain, with slow, progressive memory loss, inability to concentrate, and loss of interest in self-care. Personality changes may include irresponsible behavior, depression, delusions of grandeur, or complete psychosis.

Syphilis sometimes mimics the symptoms of HIV/AIDS. Conversely HIV/AIDS appears to increase the severity of syphilis in patients suffering from both diseases and to speed the development or appearance of neurosyphilis. Patients with both syphilis and HIV/AIDS also are more likely to develop lues maligna, a skin condition that sometimes occurs in secondary syphilis and is characterized by areas of ulcerated and dying tissue.

Infants with early congenital syphilis have systemic symptoms that resemble those of secondary syphilis in adults. The central nervous system is affected in 40–60% of children with congenital syphilis. Symptoms include:

- skin rashes
- condylomata lata
- inflammation of the lungs
- persistent runny nose

Nosode—A homeopathic remedy made from microbes, pus, or other disease material. Syphilinum is a nosode made from a diluted solution of killed *T. pallidum*.

Spirochete—A long, slender, coiled-shape bacterium, such as *T. pallidum* that causes syphilis.

Tabes dorsalis—A progressive deterioration of the spinal cord and spinal nerves that is associated with tertiary syphilis.

Treponema pallidum—The spirochete bacterium that causes syphilis.

- swollen lymph nodes
- jaundice
- enlargement of the spleen and liver
- anemia

Symptoms of late congenital syphilis develop after age two and include:

- facial deformities (saddle nose)
- Hutchinson's teeth (abnormal upper incisors)
- saber shins
- dislocated joints
- deafness
- intellectual disabilities (ID)
- paralysis
- seizure disorders

Diagnosis

Examination

Diagnosis of syphilis is often delayed:

- The initial chancre may go unnoticed.
- There are wide variations in early symptoms.
- The incubation period varies greatly.
- Patients often do not connect their symptoms with recent sexual contact.

The skin rash of secondary syphilis is sometimes the first symptom to be diagnosed. Women may be diagnosed in the course of a routine gynecological exam. While taking a medical history, the physician will ask about recent sexual contacts to determine whether the patient falls into a high-risk group. Symptoms such as skin rashes or swollen lymph nodes will be noted with respect to the timing of a patient's sexual contacts.

Tests

The definitive diagnosis of syphilis depends on laboratory test results. Various tests also are used as screens for syphilis and for follow-up monitoring after treatment. Because of the long-term risks of untreated syphilis, groups of people are routinely screened for the disease:

- marriage-license applicants
- pregnant women
- children born to infected mothers
- patients with HIV/AIDS
- sexual contacts or partners of patients diagnosed with syphilis

Nontreponemal antigen tests are used as screens for syphilis. They measure the presence of reagin, an antibody formed in reaction to *T. pallidum*. In the venereal disease research laboratory (VDRL) test, a

sample of the patient's blood serum is mixed with cardiolipin and **cholesterol**. The formation of clumps indicates a positive reaction. The serum sample can be diluted to determine the concentration of reagin in the patient's blood. The rapid plasma reagin (RPR) test is a kit in which the serum is mixed with cardiolipin on a plastic-coated card that can be examined with the naked eye. Nontreponemal antigen tests require interpretation and sometimes further testing. They can yield both false-negative and false-positive results. False negatives can occur when patients are tested too soon after exposure to syphilis, since it takes about 14–21 days for antibodies to become detectable after infection. False-positive results can be caused by other diseases, including mononucleosis, **malaria**, **leprosy**, **rheumatoid arthritis**, and lupus. Whereas the overall rate of false positives is 0.8%, the rate of false positives in HIV/AIDS patients is about 4%.

Treponemal antibody tests are used to rule out false-positive results on nontreponemal screening tests. They are more expensive and complicated than nontreponemal tests, but are very specific and sensitive. They measure the presence of antibodies that are specific for *T. pallidum*. These tests include:

- the microhemagglutination-*T. pallidum* (MHA-TP) test, in which sheep red blood cells are coated with *T. pallidum* antigen; the cells clump if the patient's blood contains specific antibodies against the antigen
- the fluorescent treponemal antibody absorption (FTA-ABS) test, in which antibodies in the blood are used to coat *T. pallidum* on a slide and a fluorescein dye causes the coated spirochetes to fluoresce under ultraviolet (UV) light
- the INNO-LIA test—the most accurate antibody test—which uses recombinant and peptide antigens derived from *T. pallidum*

T. pallidum also can be identified in samples of tissue or lymphatic fluid. Slides of fresh samples are examined under microscopic dark-field illumination or slides of dried smears are stained with fluorescein and viewed under UV light.

A high **white blood cell count** and elevated protein levels in the cerebrospinal fluid (CSF) may suggest neurosyphilis. VDRL or FTA-ABS tests of the CSF are used to diagnose:

- neurosyphilis
- congenital syphilis
- syphilis in HIV/AIDS patients
- patients who are not responding to treatment with penicillin

Patients who test positive for syphilis are tested for HIV infection at the time of diagnosis. All sexual partners of a diagnosed patient must be tested for syphilis.

Treatment

Drugs

Syphilis is treated with antibiotics, either injected intramuscularly (benzathine penicillin G or ceftriaxone) or administered orally (doxycycline, minocycline, tetracycline, or azithromycin). In the vast majority of cases a single dose of penicillin is sufficient to cure primary and secondary syphilis. Penicillin is less effective in treating later stages and additional doses may be necessary. Neurosyphilis is treated with a combination of aqueous crystalline penicillin G, benzathine penicillin G, or doxycycline. The levels of penicillin in the patient's body must be kept sufficiently high over a period of days or weeks because *T. pallidum* has a relatively long reproduction time. Follow-up blood tests should be performed every three months to confirm that the patient is completely cured.

Pregnant women with syphilis are treated with tetracycline as early in pregnancy as possible. Infants with proven or suspected congenital syphilis are treated with either aqueous crystalline penicillin G or aqueous procaine penicillin G. Children who acquire syphilis after birth are treated with benzathine penicillin G.

Jarisch-Herxheimer reaction may occur during penicillin treatment for late-primary, secondary, or early-latent syphilis. The patient develops chills, fever, headache, and muscle pains within two to six hours after the penicillin injection and the chancre or rash temporarily worsens. The reaction lasts about one day and is thought to be an allergic reaction to the toxins that are released as massive numbers of spirochetes are destroyed.

Alternatives

The historical link between homeopathy and syphilis is Hahnemann's theory of miasms, which labeled the syphilitic miasm as the second-oldest cause of constitutional weakness in humans. Homeopathic practitioners in the United States are banned from claiming that their treatments can cure syphilis. However because of the high incidence of syphilis in HIV/AIDS patients, some alternative practitioners claim that their homeopathic remedies for **AIDS** also are beneficial in treating syphilis. The most frequently suggested remedies are *Medorrhinum*, *Aurum*, *Mercurius vivus*, and *Syphilinum*. The use of *Mercurius vivus* reflects the historical use of mercury to treat syphilis. *Syphilinum* is in a class of homeopathic remedies called

nosodes, which are made from disease material, such as bacteria, viruses, or pus. *Syphilinum* is made from a dilution of killed *T. pallidum*.

Certain outdated or discredited treatments for syphilis have resurfaced as alternative treatments for HIV/AIDS and cancer. Hyperthermia—inducing a fever to treat HIV/AIDS—originated as a treatment for syphilis, in which patients were infected with malaria in an attempt to kill *T. pallidum*. The Hoxsey treatment for cancer, which is no longer legally available in the United States, was developed in the 1920s by Harry Hoxsey and prescribed as a treatment for secondary and tertiary syphilis. The treatment consists of several chemical mixtures applied externally and a formula of nine herbs taken internally. The external formulation contains both arsenic and antimony, which were used to treat syphilis before the advent of antibiotics. The internal herbal formula includes *Phytolacca americana*, or pokeweed, which was used by Native Americans to treat syphilitic chancres, and *Stillingia sylvatica*, or queensroot, which was used in the past to treat syphilis. All of these components are potentially toxic and should not be used to treat syphilis.

Traditional Chinese medicine (TCM) and other alternative approaches emphasize the mental aspects of diseases such as syphilis. Alternative practitioners may recommend mind-body medicine, **guided imagery**, and affirmations as adjuncts to antibiotic treatment for syphilis.

Home remedies

Although antibiotics are essential for the treatment of syphilis, recovery can be aided by good dietary habits, adequate sleep, **exercise**, and stress-reduction techniques. Skin rashes and ulcers should be kept clean and dry. Patients must abstain from sexual contact until their disease has been cured. Other people should not be exposed to fluid or discharges from chancres, skin ulcers, rashes, or condylomata lata.

Prognosis

Antibiotics—especially penicillin—cure early-stage syphilis quickly and effectively. Treatment failures do occur, especially in HIV/AIDS patients treated with penicillin. Patients also can be re-infected. Patients should be followed up with blood tests at one, three, six, and 12 months after treatment or until the results are negative. CSF should be tested after one year. Patients with primary and secondary syphilis who remain symptom-free and have negative blood tests for two years after treatment are usually considered cured. Patients with recurrences during the latency period should be tested for re-infection.

In patients with untreated syphilis:

- About 30% undergo spontaneous remission.
- About 30% have lifelong latency.
- About 40% develop potentially fatal tertiary forms of syphilis.

Proper treatment for maternal syphilis during the second and third trimesters of pregnancy reduces the risk of congenital syphilis in the infant from 90% to less than 2%. However nearly 50% of untreated fetuses die shortly before or after birth. Those who survive may appear normal at birth but show signs of infection between three and eight weeks of age.

Prevention

Prevention of syphilis depends on a combination of personal and public health measures. Patients with syphilis do not acquire lasting immunity against the disease, so they can be easily re-infected. The only reliable methods for preventing transmission of syphilis are sexual abstinence or a monogamous relationship between uninfected partners. **Condoms** reduce the risk of transmission but protect only the covered parts of the genitals. The general public needs to be informed about the transmission and early symptoms of syphilis and public health facilities must provide for adequate testing and treatment.

U.S. law requires the reporting of all syphilis cases to public health agencies. Sexual contacts of patients diagnosed with syphilis are traced and tested for the disease. This includes all contacts in the past three months for cases of primary syphilis and in the past year for cases of secondary syphilis. Neither patients nor their contacts should have sexual contact until they have been tested and treated. Patients should be informed about the disease and counseled regarding sexual behavior, safe sexual practices, and the importance of completing antibiotic treatment. In addition:

- Sexually active adolescents should be routinely screened for syphilis.
- Pregnant women should be tested for syphilis at the time of their first prenatal visit and again shortly before delivery.
- Many obstetricians and gynecologists recommend the routine screening of non-pregnant women.
- Because of the rising incidence of syphilis worldwide, many public health physicians recommend routine screening of immigrants, refugees, and international adoptees.

In 2006 the Centers for Disease Control and Prevention (CDC) announced an update to its "National Plan to Eliminate Syphilis in the United States":

- investing and enhancing public health services and interventions for syphilis treatment
- prioritizing and targeting interventions for high-risk populations, such as African Americans and MSM
- improving the accountability of prevention efforts

Systemic lupus erythematosus

Definition

Lupus is an autoimmune disorder that may damage body tissues and lead to widespread, chronic inflammation and **pain** during periods of worsened symptoms called flares. Lupus can cause problems with multiple body systems and organs, including the joints, skin, kidneys, heart, lungs, and blood vessels. Although lupus cannot be cured, it is treatable with medications and other therapies.

Description

Lupus is an autoimmune disease. Normally, the white blood cells in the body's immune system protect a person from harmful substances called antigens. Antigens may include bacteria, viruses, foreign blood, cancer cells, and other toxins that could cause disease or infection. To defend the body against antigens, the body produces antibodies. In a person with a healthy immune system, the antibodies then destroy the antigens, keeping the person from getting sick.

In people with autoimmune diseases, however, the immune system cannot tell the difference between an antigen and healthy tissues. As a result, the body

Systemic lupus erythematosus (SLE) is an autoimmune disease in which the individual's immune system attacks, injures, and destroys the body's own organs and tissues. Nearly every system of the body can be affected by SLE, as depicted in the illustration. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

begins attacking its own healthy tissues. In people with lupus, the autoimmune response most often attacks the joints, skin, heart, lungs, kidneys, and blood and circulatory system.

There are several different types of lupus, including: systemic lupus erythematosus (SLE); **discoid lupus erythematosus** (DLE); and drug-induced lupus. The severity of lupus symptoms vary from person to person: in some people, the symptoms may be mild and involve only the joints and skin; in others, the disease may be severe and cause joint, kidney, lung, heart, and bone complications.

Systemic lupus usually involves multiple organs and body systems and is usually more severe than the DLE form of the disease. The majority, about 70% of all lupus cases involve this systemic form of the disease. People with SLE typically experience pain in the joints and muscles, **fatigue**, and skin **rashes**, which may come and go. These periods of more severe symptoms are called flares, whereas the milder periods of the disease are referred to as remission. People with SLE may experience kidney inflammation (**nephritis**), which can make it difficult for the body to remove toxins and other waste products. Lupus patients may be prone to develop **pneumonia** or inflammation of the chest cavity that makes it difficult to breathe. The disease may also contribute to central nervous system problems, including headaches, **dizziness**, seizures, behavior changes, and vision and memory difficulties.

WWW.BOOKBAZ.IR

Having lupus also increases the risk of atherosclerosis (hardening of the arteries), **blood clots**, and deficiencies in red and white blood cells and platelets.

DLE, sometimes referred to as discoid or cutaneous lupus, primarily affects the skin and accounts for 10% of all lupus cases. People with this form of lupus typically develop a rash on the face, neck, and scalp but do not experience problems with the joints, kidneys, or heart. However, about 10% of people with DLE eventually develop SLE; doctors think that in these patients, the rash was an initial symptoms of systemic inflammation.

Drug-induced lupus may also develop after a person takes certain prescription medications. People with this type of lupus tend to have symptoms similar to those of SLE, but the symptoms of lupus typically fade within days, weeks, or months of discontinuing the medications. Medications that may induce lupus include hydralazine (a drug used to treat high blood pressure) and procainamide (a drug used to treat irregular heart rhythms). About 4% of people who take these medications develop drug-induced lupus.

Demographics

Lupus affects people of all ages and races, but it is most common in women. Ninety percent of the 1.4 million diagnoses of lupus in the United States are made in women. Lupus is also more prevalent among younger women between 15 and 44 and women of particular ethnic groups. Hispanic/Latino, African American, and American Indian women are more likely to develop lupus than white women, and their symptoms tend to be more severe.

However, according to the Lupus Foundation of America, 15% of people with SLE develop it later in life—after age 55. Late onset lupus affects women eight times more than men, and is more prevalent in Caucasians, although it can occur in people of any race.

Drug-induced lupus is also more common in older adults because of the greater likelihood that they have other conditions (such as **heart disease** and high blood pressure) that require medication. When a person goes off the medication, the symptoms of drug-induced lupus eventually go away.

Causes and symptoms

The cause of SLE is unknown. Because the vast majority of patients are women, some research is being done to determine what (if any) link the disease has to female hormones. SLE may have a genetic basis, although more than one gene is believed to be involved in the development of the disease. Because lupus often runs in families, researchers think there is a genetic component to the disease. However, other factors, including environment, **stress**, the use of certain medications, and exposure to sunlight, may also influence lupus development and exacerbate flares.

Symptoms of lupus depend on the type a person has and can vary widely. Some common symptoms of lupus include:

- a signature red rash or color change in the skin across the nose and cheeks (this is also called a malar rash; often it is in the shape of a butterfly)
- painful, swollen joints (arthritis) and glands
- fevers that can't be explained by illness
- pain in the chest when breathing
- extreme fatigue
- anemia (loss of red blood cells)
- hair loss
- sensitivity to the sun
- blood flow problems in the fingers when cold or stressed
- depression
- problems with memory or thinking clearly

For some people, mouth sores, seizures, **hallucinations**, and kidney problems signal lupus.

In people with late-onset lupus, symptoms tend to be milder and include arthritis, **pleurisy**, **pericarditis**, dry eyes and mouth, and muscle aches. In older adults, it may be harder to diagnose lupus because the symptoms mimic other diseases common in this age group, such as **rheumatoid arthritis**.

Lupus symptoms may come and go. These periods of worsened symptoms, called flares, may be triggered by spending time in the sun or during a time of emotional stress.

SLE has also been linked to a higher risk of developing **osteoporosis**, a disease that makes bones brittle and more likely to break. Osteoporosis may occur in lupus patients because the steroid medications often prescribed to reduce inflammation can lead to bone loss. Fatigue and pain in the joints and muscles also makes it more likely a person will remain inactive, which increases the likelihood of bone loss. Finally, lupus itself may contribute to weakened bones that are more likely to break.

According to the National Institute of Arthritis and Musculoskeletal and Skin Diseases, women with lupus may have more than five times the risk of a bone fracture from osteoporosis.

The severity of a patient's SLE varies over time. Patients may have periods with mild or no symptoms, followed by a flare. During a flare, symptoms increase in severity and new organ systems may become affected.

Many SLE patients have fevers, fatigue, muscle pain, weakness, decreased appetite, and weight loss. The spleen and lymph nodes are often swollen and enlarged. The development of other symptoms in SLE varies, depending on the organs affected.

- Joints. Joint pain and problems, including arthritis, are very common. About 90% of all SLE patients have these types of problems.
- Skin. A number of skin rashes may occur, including a red butterfly-shaped rash that spreads across the face. The "wings" of the butterfly appear across the cheekbones, and the "body" appears across the bridge of the nose. A discoid, or coin-shaped, rash causes red, scaly bumps on the cheeks, nose, scalp, ears, chest, back, and the tops of the arms and legs. The roof of the mouth may develop sore, irritated pits (ulcers). Hair loss is common. SLE patients tend to be very easily sunburned (photosensitive).
- Lungs. Inflammation of the tissues that cover the lungs and line the chest cavity causes pleuritis, with fluid accumulating in the lungs. The patient frequently experiences coughing and shortness of breath.
- Heart and circulatory system. Inflammation of the tissue surrounding the heart causes pericarditis; inflammation of the heart itself causes myocarditis. These heart problems may result in abnormal beats (arrhythmias), difficulty pumping the blood strongly enough (heart failure), or even sudden death. Blood clots often form in the blood vessels and may lead to complications.
- Nervous system. Headaches, seizures, changes in personality, and confused thinking (psychosis) may occur.
- Kidneys. The kidneys may suffer significant destruction, with serious life-threatening effects. They may become unable to adequately filter the blood, leading to kidney failure.
- Gastrointestinal system. Patients may experience nausea, vomiting, diarrhea, and abdominal pain. The lining of the abdomen may become inflamed (peritonitis).
- Eyes. The eyes may become red, sore, and dry. Inflammation of one of the nerves responsible for vision may cause vision problems, and blindness can result from inflammation of the blood vessels (vasculitis) that serve the retina.

Diagnosis

Obtaining a lupus diagnosis can be difficult for several reasons: the symptoms of lupus flare and disappear over long periods of time; the severity and type of lupus symptoms can vary widely from person to person; and finally, there is no one test that can diagnose the disease. Instead, doctors must rely on several diagnostic techniques to confirm a lupus diagnosis, including a detailed medical history, **physical examination**, blood and urine tests, and skin or kidney biopsies.

Many of the symptoms and laboratory test results of SLE patients are similar to those of patients with different diseases, including rheumatoid arthritis, **multiple sclerosis**, and various nervous system and blood disorders.

When conducting a medical history, doctors may ask patients a variety of questions, such as:

- Have you had stiff, tender, and swollen joints? Is this worse in the morning?
- Do you ever feel extremely tired for days or weeks, even when you're getting plenty of sleep at night?
- Have you ever felt pain in your chest when taking deep breaths?
- Does your skin break out when you're in the sun, but not from sunburn?
- Have you had a rash across your nose and cheeks? Is it in the shape of a butterfly?

In addition to taking a thorough medical history, doctors will also conduct a physical examination. A physician may listen to the heart (in some lupus patients, doctors can hear a sound called a heart friction rub) and conduct a **neurological exam**.

Laboratory tests are also an integral part of the lupus diagnosis process. One test, called the antinuclear antibody (ANA) test, is often checked when a doctor suspects a person has lupus. In this test, a person's blood is checked for autoantibodies that are often present in the blood of people with lupus. Testing positive for ANA does not automatically mean a person has lupus, but it can help doctors make a diagnosis when considered with a person's physical symptoms. Other tests doctors may use to confirm a lupus diagnosis include the anti-double strand DNA (dsDNA), anti-Smith antibodies (Sm), **erythrocyte sedimentation rate** (ESR), and **C-reactive protein** binding. SLE patients tend to have low numbers of red blood cells (anemia) and low numbers of certain types of white blood cells. The ESR, a measure of inflammation in the body, tends to be quite elevated.

WWW.BOOKBAZ.IR

Also, samples of tissue (biopsies) from affected skin and kidneys may show characteristics of the disease.

A test called the lupus erythematosus cell preparation (or LE prep) test is also performed. This test involves obtaining a sample of the patient's blood. Cells from the blood are damaged in the laboratory in order to harvest their nuclei. These damaged cells are then put together with the patient's blood serum, the liquid part of blood separated from the blood cells. Antinuclear antibodies within the patient's serum will clump together with the damaged nuclear material. A material called Wright's stain will cause these clumps to turn blue. These stained clumps are then reacted with some of the patient's white blood cells, which will essentially eat the clumps. LE cells are the white blood cells that contain the blue clumps. This test will be positive in about 70–80% of all patients with SLE.

The American Rheumatism Association developed a list of symptoms used to diagnose SLE. Research supports the idea that people who have at least four of the eleven criteria (not necessarily simultaneously) are extremely likely to have SLE. The criteria are:

- butterfly rash
- discoid rash
- photosensitivity
- mouth ulcers
- arthritis
- inflammation of the lining of the lungs or the lining around the heart
- kidney damage, as noted by the presence of protein or other abnormal substances called casts in the urine
- seizures or psychosis
- the presence of certain types of anemia and low counts of particular white blood cells
- the presence of certain immune cells, anti-DNA antibodies, or a falsely positive test for syphilis
- the presence of antinuclear antibodies

If lupus is diagnosed, doctors may check a person's urine for signs of kidney problems, order chest x-rays for signs of inflammation in the lungs or heart, and have the patient's blood checked for problems with the white blood cells to see how far the disease has progressed.

Treatment

Several types of healthcare professionals may work together to treat an individual with lupus. Family doctors or internists, rheumatologists (specialists in rheumatic diseases), immunologists (specialists in immune system disorders), and other specialists may play a role in treating the lupus patient.

The treatment a person receives for lupus depends on the type of lupus and the extent and severity of the disease. Both over-the-counter and prescription medications may be recommended, such as:

- Nonsteroidal anti-inflammatory drugs (NSAIDS): These drugs, which include ibuprofen and naproxen, reduce inflammation and control pain, swelling, and fever. However, these medicines also may cause side effects such as nausea, heartburn, and diarrhea as well as liver, kidney, and neurological complications with prolonged use, so it is important that a person taking these drugs for lupus does so under the direction of a doctor.
- Antimalarial drugs: Antimalarial drugs such as hydroxychloroquine treat the fatigue, joint pain, rashes, and lung inflammation caused by lupus and may prevent flares from occurring. Side effects include nausea and, in rare cases, vision problems.
- Corticosteroids: A variety of corticosteroid medications, including prednisone, hydrocortisone, methylprednisolone, and dexamethasone, can suppress the inflammation often associated with lupus. Lupus patients take these drugs in pill form, apply creams to the skin, or receive corticosteroid injections. Despite their effectiveness, corticosteroid drugs do have short-term side effects, such as increased appetite and weight gain. Long-term side effects may include high blood pressure, weakened bones, artery damage, diabetes, and cataracts.
- Immunosuppressive agents: These drugs, including azathioprine, cyclophosphamide and mycophenolate mofetil, block the production of immune cells and are typically used in lupus patients who experience kidney or central nervous system problems. A person taking immunosuppressive drugs may experience nausea and vomiting, as well as bladder problems, hair loss, decreased fertility, and an increased risk of infection.

Doctors may also use arthritis drugs to help control symptoms of lupus and reduce the risk of flares.

Other treatments for SLE try to help specific symptoms. Clotting disorders will require blood thinners. Psychotic disorders will require specific medications. Kidney failure may require the blood to be cleaned outside the body through a machine (dialysis) or even a **kidney transplantation**.

Alternatives

Medications for lupus are costly, and many have the potential for serious adverse side effects. As a

KEY TERMS

Antinuclear antibody (ANA) test—A test often used to look for autoantibodies that react against components of the nucleus of the body's cells. Many people with lupus test positive for ANA.

Arthritis—A condition characterized by inflamed, swollen, painful joints.

Autoimmune disorder—A disorder in which the body's antibodies mistake the body's own tissues for foreign invaders. The immune system then attacks and causes damage to these tissues.

Chromosomes—Spaghetti-like structures located within the nucleus (or central portion) of each cell. Chromosomes contain genes, structures that direct the growth and functioning of all the cells and systems in the body. Chromosomes are responsible for passing on hereditary traits from parents to child.

Immune system—The system of specialized organs, lymph nodes, and blood cells throughout the body that work together to prevent foreign organisms (bacteria, viruses, fungi, etc.) from invading the body.

Nephritis—Inflammation of the kidneys.

Osteoporosis—A condition that makes bones less dense and more likely to fracture.

Pericarditis—Inflammation of the sac around the heart.

Pleurisy—Chest pain that occurs when a person takes a deep breath.

Psychosis—Extremely disordered thinking with a poor sense of reality; may include hallucinations (seeing, hearing, or smelling things that are not really there).

result, some patients turn to other therapies to relieve lupus symptoms.

Massage and **acupuncture** are just a few of the alternative and complementary therapies that may be used by lupus patients. Doctors may encourage lupus patients to get regular, gentle **exercise** during remission to increase joint flexibility and muscle strength. Stress management is key for people with SLE and such techniques as **meditation**, **hypnotherapy**, and **yoga** may be helpful in promoting relaxation.

In addition, some patients have tried dietary supplements in an attempt to alleviate lupus symptoms. Supplementation with **omega-3 fatty acids** found in fish oils could hold promise for lupus patients. In one study of 60 people with SLE, daily doses of 3 grams of omega-3 fatty acids in the form of fish oil supplements over a 6-month period improved lupus symptoms. Not only did the supplements appear to relieve joint pain, but they also improved blood vessel function, researchers noted.

Other dietary suggestions include eating a whole foods diet with reduced amounts of red meat and dairy products in order to decrease pain and inflammation. **Food allergies** are believed either to contribute to SLE or to arise as a consequence of the digestive difficulties. Wheat, dairy products, and soy are the major offenders. An elimination/challenge diet can help identify the offending foods so that they can be avoided. Because alfalfa sprouts have been associated with the onset of flares in SLE, they should be avoided. Supplements that have been suggested to improve the health of SLE patients include **vitamins** B, C, and E, as well as selenium, zinc, magnesium, and a complete trace mineral supplement. **Vitamin A** is believed to help improve discoid skin rashes. Botanical medicine can help the entire body through immune modulation and **detoxification**, as well as assisting individual organs and systems. Homeopathy and flower essences can work deeply on the emotional level to help people with this difficult disease.

Nutrition

There are no specific guidelines for people with lupus to follow, however, there are several nutritional considerations that may be impacted by a lupus diagnosis.

Lack of appetite and weight loss is common among people who have recently been diagnosed with lupus. Appetite and weight loss may be related to a person's symptoms of pain and fatigue, or they may be a side effect of common lupus medications. In addition, some people develop mouth sores when taking lupus medications, another factor that can make it difficult to eat. Older adults struggling with a lack of appetite should talk to their healthcare providers, who may recommend consulting with a registered dietitian who can suggest a diet that works best with the patient's needs and lifestyle.

Weight gain is also a common side effect of **corticosteroids**, drugs that are often used to treat the

WWW.BOOKBAZ.IR

inflammation of lupus. If a person has gained weight after starting lupus medications, a registered dietitian (RD) can also help by devising a meal plan that incorporates nutritious foods that won't add excess weight. A RD can also help lupus patients work toward controlling high blood pressure and avoiding atherosclerosis. These cardiovascular complications may be more common in lupus patients, but a combination of a low-fat diet and exercise may reduce the risk of these common complications.

Also, lupus patients taking corticosteroids may need to take **vitamin D** and **calcium** supplements to counteract the bone-damaging effects of the disease and reduce the risk of osteoporosis.

In general, if medication use or lupus symptoms are making it difficult to eat, patients should consult with a doctor or nurse, who can provide additional information.

Prognosis

The prognosis for patients with SLE varies, depending on the organ systems most affected and the severity of inflammation. Some patients have long periods of time with mild or no symptoms. About 90–95% of patients are still living after 2 years with the disease. About 82–90% of patients are still living after 5 years with the disease. After 10 years, 71–80% of patients are still alive, and 63–75% are still alive after 20 years. The most likely causes of death during the first 10 years include infections and kidney failure. During years 11–20 of the disease, the most likely cause of death involves the development of abnormal blood clots.

Because SLE frequently affects women of childbearing age, **pregnancy** is an important issue. For pregnant SLE patients, about 30% of the pregnancies end in **miscarriage**. About 25% of all babies born to mothers with SLE are premature. Most babies born to mothers with SLE are normal. However, a rare condition called neonatal lupus causes a baby of a mother with SLE to develop a skin rash, liver or blood problems, and a serious heart condition.

The Centers for Disease Control and Prevention estimate that more than 1,000 people die from lupus annually, and older adults, women, and blacks had the highest death rates among lupus patients. Following the doctor's instructions, taking medications exactly as they are prescribed, and getting help when symptoms flare can help lupus patients extend the quantity and quality of their lives.

Prevention

There are no known ways to avoid developing SLE. However, it is possible for a patient who has been diagnosed with SLE to prevent flares of the disease. Recommendations for improving general health to avoid flares include decreasing sun exposure, getting sufficient sleep, eating a healthy diet, decreasing stress, and exercising regularly. It is important for a patient to try to identify the early signs of a flare (like **fever**, increased fatigue, rash, **headache**). Some people believe that noticing and responding to these warning signs will allow a patient with SLE to prevent a flare, or at least to decrease its severity. In addition, getting regular health care and laboratory tests can help doctors note changes and make adjustments once a flare begins. Finally, because they are at risk for other complications from lupus, older adults should have their blood pressure and **cholesterol** checked regularly. An annual **influenza** vaccine may also be recommended, and patients should reduce exposure to the sun and always wear sunscreen.

Tai chi

Definition

Tai chi is a Chinese **exercise** system that uses slow, smooth body movements to achieve a state of relaxation of both body and mind.

Purpose

As a system of physical exercise used to improve and maintain health, tai chi can be helpful in achieving a state of physical and mental relaxation while also strengthening the cardiovascular and immune systems.

Precautions

As a very slow and gentle form of moving, tai chi has virtually no side effects. However, if a person has any doubts about the conditions of his or her joints, vertebrae, or heart, a physician should be consulted.

Description

Developed originally in China as a self-defense strategy, or martial art, tai chi—the "supreme ultimate fist"—is practiced in modern times primarily as a gentle exercise technique. Described as "meditation in motion," tai chi consists of a standing person performing a series of postures or bodily movements in a slow and graceful manner, with each movement flowing without pause to the next. According to Chinese legend, the technique was created by a Taoist monk who was inspired as he watched a crane and a snake do battle. Impressed by the snake's ability to subtly and swiftly avoid the bird's thrusts, he devised a series of self-defense techniques that do not involve meeting the opponent's force with force, but rather **stress** evading the blow; causing the opponent's own momentum to work against him.

Tai chi is an ancient form of exercise, about 2,000 years old, that at one point had over 100 separate movements or postures. In current practice, there are two popular versions, of 18 and 37 movements respectively. The fact that in China 10 million people practice some type of tai chi daily suggests that it is one of the most popular forms of exercise in the world. In the United States, tai chi is learned in classes in which students (or "players," as they are called in China) wear loose, comfortable clothing and either go barefoot or wear only socks or soft shoes on the feet. In China, tai chi is almost always practiced outdoors at dawn, and ideally near trees. Unlike other martial arts, tai chi is not competitive. Classes usually begin with a few minutes of standing **meditation** to calm the mind and gather energy. Following warm-up exercises, students are taught the basics of a particular form or posture. Learning forms is not easy, and it takes some time to master what looks like a simple position. Properly done postures are done in a relaxed, artful, and linked way, with the circular and rhythmic movements of one position flowing seamlessly into the next.

While strict attention to body position is critical, proper breathing is considered to be equally important. Just as movements are slow and continuous and without strain, breathing should be effortless yet deep. Finally, both mental and physical balance is considered essential to tai chi. The experienced practitioner of tai chi maintains perfect body balance throughout the exercise series. Altogether, the five essential qualities of tai chi are:

- Slowness. To develop awareness.
- Lightness. To make movements flow.

KEY TERMS

Arthritis—Inflammation of the joints.

Cardiovascular—Relating to the heart and blood vessels.

Continuity—Uninterrupted and successive.

Fibromyalgia—A chronic disease syndrome characterized by fatigue, widespread muscular soreness, and pain at specific points on the body.

Meditation—An exercise of contemplation that induces a temporary feeling of relaxation.

Stamina—Staying power, endurance.

Yoga—A system of exercise aimed at promoting the control of the body and the mind.

- Balance. To prevent body strain.
- Calmness. To maintain continuity.
- Clarity. To focus the mind.

Tai chi has both physical and mental benefits. If done regularly, it improves muscle tone, flexibility, balance, and coordination. Many older people find that it boosts their energy, stamina, and agility, sharpens their reflexes, and gives an overall sense of well-being. The calming and meditative aspects of tai chi allow many to experience its ability to relieve stress. Some claim tai chi to be a healing therapy, and it is often used to support other treatments for chronic conditions; arthritis, **fibromyalgia**, and digestive disorders are just three examples. Like **yoga**, tai chi has several different styles to suit the individual. Also, it can eventually be done daily by oneself, and ultimately becomes a very personal endeavor. Most Westerners find it best to practice tai chi in the same place and at the same time of day; and those who enjoy it most are those who are not seeking major, dramatic breakthroughs, but rather who can take pleasure in small gains that accumulate over a long period of time.

Some research done in the United States focuses on the emotional and psychological benefits of tai chi. One recently discovered advantage of tai chi is its ability to hold people's interest longer than many other forms of exercise. One study in Oregon found that only 20% of people enrolled in a six-month tai chi program dropped out before the end, compared to an average of 55% for other forms of exercise. With regard to depression, a study of college students found that those who were taking tai chi classes had a lower rate of depression than students enrolled in other fitness programs.

Risks

Tai chi is a safe exercise system for people of all ages and fitness levels. Done properly, without any over-stretching, tai chi should not leave a person feeling tired or sore.

Results

Besides its overall fitness benefits and **stress reduction** aspects, regular tai chi sessions are said to be especially helpful for seniors, as they lower their blood pressure. Tai chi claims to benefit people with arthritis, those recovering from an injury or rehabilitating their hearts, and also improves balance, and reduces the risk of falling, especially important for the elderly. Tai chi can result in a significant improvement in the quality of life for anyone. But, because of the low stress level of the exercises it is a particularly attractive form of exercise to seniors.

In addition to studying the cardiovascular and range-of-motion benefits of tai chi, researchers are also investigating its positive effects on the immune system. A team of scientists in California reported in 2003 that tai chi boosts the resistance of older people to the **shingles** virus—a virus that is both more common and more severe in the elderly.

Tanning

Definition

Tanning is the browning or darkening of skin from exposure to ultraviolet (UV) radiation, either from sunlight or from an artificial source.

Purpose

Many people consider tanning fashionable and pursue it for cosmetic purposes. Most Americans—including up to 80% of young people under age 25—believe that a tan improves their appearance. Tanning beds or "sunbeds" that darken the skin using UV–radiating lights have become increasingly popular throughout the developed world, especially among young women. Many people also believe that tanning prevents **sunburn**.

Everyone needs some exposure to sunlight to produce vitamin D_3 or cholecalciferol, which is synthesized in the skin after exposure to ultraviolet B (UV-B) light and converted into the active form of **vitamin D**. Vitamin D is required for **calcium** absorption for strong, healthy bones, as well as for a variety of other bodily functions. Light-colored skin absorbs more UV-B than darker skin. It has been postulated that lighter–colored skin evolved as humans migrated to northern climates with less year–round sunlight, which required maximizing absorbance of UV–B for synthesizing vitamin D. However, only 10–15 minutes of direct sunlight three times per week is adequate to meet the body's vitamin D requirement.

Demographics

Most people get 50–80% of their lifetime sun exposure during childhood—before the age of 18. Teenage girls and young women account for much of the growth in the tanning–bed industry. Sun exposure, tanning, and especially sunburn, before the age of 15, are strongly associated with the development of **melanoma** and other forms of **skin cancer**. The incidence of skin cancer is reaching epidemic proportions in the United States, at a time when the incidence of many other types of cancer is leveling off or declining.

Skin cancers account for one-third of all cancers worldwide. Each year some 132,000 new cases of malignant melanoma—the deadliest form of skin cancer—and more than 2 million cases of other skin cancers are diagnosed around the world. More than 50,000 new cases of melanoma and more than 1 million new cases of other skin cancers are diagnosed each year in the United States. The incidence of melanoma is increasing

faster than that of any other cancer. In the past, melanoma primarily affected people over age 50; however, it has become the second most common cancer among 15–29-year-olds, especially females. Other types of skin cancer are also being diagnosed more often in younger patients, including teens. Whereas older patients generally develop skin cancer on their heads and necks, young people more often develop skin cancer on their torsos. The torso is the most common location for melanoma in young women. It is suspected that this is due to high–risk outdoor and indoor tanning.

Description

Tanned skin is often associated with healthy outdoor activities and vacations in sunny climes. Unfortunately, tanning is also an indication of damaged skin. Two types of UV radiation from the sun reach the skin. UV-B affects the upper layers of skin or epidermis and is responsible for sunburn; however, most UV-B rays from the sun are absorbed by the ozone layer surrounding the earth. Therefore, the majority of ultraviolet exposure is to ultraviolet A (UV-A), which passes through window glass. Tanning beds generally use UV-A, although full-spectrum tanning lights include UV–B. UV–A radiation penetrates to the lower layers of the epidermis, where it triggers cells called melanocytes to produce a brown pigment called melanin, which is responsible for tanning. Darker-skinned people tan more deeply than light-skinned people because their melanocytes produce more melanin.

Although melanin can protect skin from burning because the pigment absorbs UV radiation, it does not protect against skin cancer and other problems. UV-A radiation can turn melanocytes cancerous, causing melanoma. UV-A also causes skin **aging** and wrinkling. UV-A can penetrate through the epidermis to the dermis, which contains blood vessels and nerves, and there UV-A can suppress the immune system, reducing its ability to protect against the development and spread of skin cancer. In addition to sunburn, UV-B rays can cause **cataracts** (clouding of the eye lens) and immune system damage, as well as contributing to skin cancer. Melanoma is thought to be associated with severe UV-B sunburns before age 20. UV radiation damages DNA in skin cells and, although the cells can repair this damage, excessive UV exposure eventually causes the damage to outpace the repair system. Both types of UV radiation, whether from the sun or from artificial sources such as tanning beds and sunlamps, are classified as known **carcinogens**.

The U.S. Food and Drug Administration (FDA) and the American Academy of Dermatology (AAD) classify skin into six types based on susceptibility to tanning and burning:

- I—extremely sun–sensitive—always burns easily and never tans
- II—very sun–sensitive—usually burns easily and tans only minimally
- III—sun–sensitive—sometimes burns and gradually tans to light brown
- IV—minimally sun–sensitive—burns minimally and always tans to moderate brown
- V—sun–insensitive—rarely burns and tans well
- VI—sun–insensitive—never burns and is deeply pigmented

Sunless tanning products, also called self-tanners, usually have dihydroxyacetone (DHA) as the active ingredient. DHA reacts with dead cells in the outermost layer of the skin to darken it. Although the color does not wash off, it fades as dead skin cells slough off, usually within a few days. These products are available as creams, gels, lotions, and sprays. Professional spray-on or airbrush tanning is also available. Although sunless tanning products are considered to

Melanin—Skin pigment that, responsible for tanning.

Melanocyte—An epidermal skin cell that produces melanin.

Melanoma—A rapidly spreading and deadly form of cancer that usually occurs on the skin.

Ozone—A type of oxygen gas that occurs in a layer about 15 mi. (24 km) above Earth's surface and that helps protect living organisms from the damaging effects of the sun's ultraviolet rays.

SPF—Sun protection factor; a number assigned to sunscreens that indicates the amount of UV-B radiation that is required to produce sunburn in the presence of the sunscreen, relative to the amount of UV–B radiation required to burn unprotected skin.

Sunblock—A skin preparation containing an active ingredient, such as titanium oxide, that prevents sunburn by physically blocking out ultraviolet radiation.

Sunscreen—A skin preparation containing an active ingredient, such as benzophenone, that prevents sunburn by chemically absorbing ultraviolet radiation.

Ultraviolet radiation; UV—Invisible light rays with wavelengths shorter than those of visible light, but longer than those of x rays.

Vitamin D—Any of several fat–soluble vitamins that are required for normal bone and teeth structure and various other physiological functions. Vitamin D is obtained from some foods and is produced in the body through the action of ultraviolet radiation.

be safe for applying to the skin, sunless tanning pills are unsafe. They usually contain the color additive canthaxanthin that, in large amounts, can turn the skin orange and cause **hives**, liver damage, and the formation of crystals in the retina of the eye.

Origins

Tanning has not always been considered desirable. In the past, tanning was often associated with outdoor manual labor and poverty. Then, in the 1920s, the designer Coco Chanel returned from a vacation on the Riviera with a deep tan. Tanning suddenly became fashionable and a symbol of wealth and leisure.

Common problems

Tanning can put a child at risk for sunburn, short-term or long-term eye damage, premature skin aging, immune system suppression, and the eventual development of skin cancer. Sunburns, especially blistering sunburns during childhood or adolescence, increase the risk of developing melanoma. Some experts believe that melanoma on the legs and trunk may result from sun exposure during childhood, since these areas are less often exposed to sunlight during adulthood. Tanning booths can contribute to the development of melanoma anywhere on the body.

Experts now generally believe that all tanning damages the skin and that no degree of tanning can be considered safe. Along with the World Health Organization (WHO), the AAD supports a ban on indoor tanning by minors. The AAD also supports banning the manufacture and sale of indoor tanning equipment for non–medical purposes. Tanning salons are often unregulated and many fail to provide supervision or eye protection. In a National Cancer Institute–supported study published in 2009, female college students posed as fair-skinned, 15-year-olds who had never tanned. They telephoned more than 3,600 tanning facilities in all 50 states and inquired about their procedures. Fewer than 11% of the facilities followed the recommended schedule of no more than three sessions during the first week. Furthermore, 71% of the facilities promoted unlimited tanning packages and said that they would allow a teenager to tan every day during the first week.

Parental concerns

Parents should not promote tanning by their children and teens. It is particularly important to prevent sunburns in young children by limiting sun exposure and using sunscreen or sunblock. The AAD recommends that children with all skin types use water–resistant sunscreen with a sun protection factor (SPF) of at least 15 throughout the year, even on days when it is cool, windy, or cloudy. Sunscreen should be used even when very little time is spent outdoors, because up to 80% of sun exposure occurs during incidental day-to-day activities, rather than planned outside excursions. Unprotected skin can be damaged by as little as 15 minutes of sun exposure, although sunburn is sometimes not apparent until at least 12 hours later.

WWW.BOOKBAZ.IR

Broad-spectrum sunscreen protects against both UV-A and UV-B rays. Titanium oxide is a sunblock that is appropriate for children with sensitive skin.

Babies have very thin, very sensitive skin and underdeveloped melanocytes. Infants under six months should be kept in the shade, with their entire bodies covered. A minimal amount of sunscreen that is approved for babies under six months of age may be applied to the face and hands.

Sunscreen should be applied 15–30 minutes before going outdoors and reapplied every two hours and after swimming or sweating. Waterproof **sunscreens** may last up to 80 minutes in the water and some sunscreens are also sweat–and rub–proof. Studies have found that most people use only 25–50% of the recommended amount of sunscreen. One ounce (28 g) is considered the proper amount for covering exposed portions of the body.

UV rays reflect off snow, sand, and water, increasing the likelihood of sunburn. Other concerns include certain medications—especially some **antibiotics** and **acne** medications—that can cause any type of skin to burn very easily. Some cosmetics also can increase sensitivity to UV radiation.

Children should:

- stay out of the sun between 10 a.m. and 4 p.m., when the sun is strongest, especially in the summer, at lower latitudes, and at high altitudes
- wear cool, lightweight, cotton clothing that covers the arms and legs
- wear sun-blocking shirts for swimming
- wear wide-brimmed hats that shade the face, scalp, ears, and neck
- wear sunglasses
- use a beach umbrella or pop-up tent for playing in the sun

Children and teens should never use tanning beds or sunlamps. Many states restrict the use of tanning beds by minors or require parental consent; however these restrictions are often ignored by tanning facilities. Sunscreen should be used in conjunction with sunless self-tanning products.

Tapeworm diseases

Definition

Tapeworms are a group of parasitic worms that live in the intestinal tracts of some animals. Several different species of tapeworms can infect humans. Tapeworm disease or cestodiasis occurs most commonly after eating raw or undercooked meat or fish that contains the immature form of the tapeworm.

Description

Tapeworm infections pose a serious **public health** problem in many less developed countries due to poor sanitation conditions. The disease is most common where livestock, such as cattle and pigs, are raised in areas where human feces are not disposed of in a sanitary manner. Another common source of human tapeworms is certain species of freshwater fish.

Tapeworm infections tend to occur more frequently in areas of the world where the people regularly eat raw or undercooked beef, pork, or fish. Persons of all ages and both sexes are susceptible to tapeworm infection, but children are generally not exposed until they are old enough to begin eating meat or fish.

Tapeworm infections in humans are less common in industrialized regions of the world, although German public health experts reported in 2003 that the rate of these infections is higher in Europe than the official statistics indicate. Travel to areas where tapeworm infections are more common and immigration of people from these areas serve as new sources of the parasite. Infected persons are often unaware of the presence of adult tapeworms in their intestinal tract, as they may have no obvious symptoms of infection. Some tapeworms can live in an infected person for over 10 years if diagnosis is not made and treatment is not administered.

In addition to the typical infection caused by eating undercooked meat or fish, people may also be directly infected by ingesting tapeworm eggs shed by the adult worm. This type of tapeworm infection can lead to a condition referred to as cysticercosis, in which the larvae continue to develop within tissues other than the intestinal tract. One of the most serious forms of this disease occurs when the tapeworm larvae infect the central nervous system, a disease referred to as neurocysticercosis. In contrast to a typical tapeworm infection, which may not be associated with symptoms, neurocysticercosis is a serious condition that may cause seizures and is potentially life-threatening.

Causes and symptoms

Several species of tapeworm can infect people. The two most common species are the pork tapeworm (*Taenia solium*) and the beef tapeworm (*T. saginata*). Improperly treated human sewage may be used to fertilize pastures or crops. Pigs or cattle become infected by grazing in contaminated pastures or drinking water contaminated with tapeworm eggs from human feces. The pea-sized larvae of these tapeworms are deposited in certain tissues of the body of infected pigs and cattle, including the muscles. The infection is then transmitted to people when raw or undercooked meat containing tapeworm larvae is consumed. The immature tapeworm develops into the adult form in the human intestine and may remain there for many years if not identified and treated.

The *Taenia* tapeworms attach to the intestinal walls but cause only mild inflammation at the site of attachment. As a result, most tapeworm carriers

show no symptoms (asymptomatic) and usually become aware of the infection only after noticing tapeworm segments in their feces. Segments of the beef tapeworm may spontaneously pass through the anus causing a noticeable sensation. Mild gastrointestinal symptoms, such as nausea or abdominal **pain**, can occur in infected individuals. In rare cases where the tapeworm segments migrate into the appendix, pancreas, or bile duct, there may be a sudden onset of severe abdominal discomfort.

Cysticercosis is a potentially serious complication of *T. solium* infection in which the larvae develop outside the intestinal tract. This type of infection is less common and occurs following accidental consumption of tapeworm eggs released from the adult worm. These eggs initially are localized in the anal area, but they may also contaminate the fingers or other parts of the body. Infection can occur in the person harboring the adult tapeworm or in other people with whom that individual comes in contact. The tapeworm larvae may develop in various tissues throughout the body. The most serious clinical problems occur when the larvae develop in the central nervous system (neurocysticercosis), potentially causing seizures and other neurological problems. An important aspect of this type of infection is that poor hygiene on the part of the individuals harboring an adult tapeworm can lead to an infection in an individual who may never consume meat. This is a particular problem if infected individuals are employed as food handlers.

Another important tapeworm that may infect people is the fish tapeworm (*Diphyllobothrium latum*). This is a frequent human intestinal parasite in many areas where raw freshwater fish is consumed. Human infection with the fish tapeworm is referred to as diphyllobothriasis. Feces from infected hosts or raw sewage contaminates a fresh water source. Tapeworm larvae are initially ingested by freshwater crustaceans and then are eaten by fish. Human infection occurs when a person consumes raw fish contaminated with the tapeworm larvae. Adult tapeworms then develop in the human intestinal tract.

Most infections with the fish tapeworm are not associated with symptoms. The tapeworm causes little damage to the lining of the intestine. Infected individuals may report **diarrhea**, **fatigue**, weakness, or sensation of hunger more commonly than uninfected individuals. One problem unique to this tapeworm is that it may compete with the host for absorption of vitamin B_{12} from the small intestine, causing the person to become deficient in this vitamin and leading to a condition called **pernicious anemia**.

Two smaller species of tapeworms may also infect people. The dwarf tapeworm (*Hymenolepis nana*) is a common infection throughout the world that can be passed from one person to another. Transmission is usually the result of inadvertent ingestion of tapeworm eggs from feces eliminated by infected individuals. As a result, infection with this tapeworm is encountered most frequently in children, the developmentally disabled, and psychiatric patient populations. Abdominal pain that is not localized to any particular area is the most common complaint. Patients may experience loose bowel movements or diarrhea with mucus, but bloody diarrhea is rare.

Another small tapeworm capable of infecting people is the rodent tapeworm (*Hymenolepis diminuta*). Rats, mice, and other rodents are the usual hosts for the adult tapeworm (definitive host), but humans can become infected following accidental consumption of insects containing tapeworm larvae. Meal worms or grain beetles that infest cereal, flour, or dried fruit are the most likely source of infection. Most human infections are not associated with symptoms, although some individuals report headaches, anorexia, nausea, and diarrhea.

Diagnosis

Identification of tapeworm segments or eggs in a stool sample is necessary for diagnosis of an adult tapeworm infection. In many cases, a tentative diagnosis may be made on the basis of a patient's description

of short chains of tapeworm segments in their stool. Further evaluation is recommended to determine the actual species involved since infection with *T. solium* is potentially more serious due to the added risk of cysticercosis. Whenever possible, tapeworm segments should be carefully collected in water or salt solutions, using strict precautions to avoid contamination. Stool examination should be performed in a laboratory having experience in the diagnosis of intestinal parasites. It is recommended that at least three stool samples be collected on alternate days to increase the likelihood of being able to make an accurate diagnosis.

Although the general appearance of tapeworm segments from the two *Taenia* species is quite similar, trained laboratory personnel can detect distinct differences between the beef and pork tapeworms when samples are examined under a microscope. Tapeworm segments and eggs from the fish tapeworm and the dwarf tapeworm have characteristic appearances that allow accurate differentiation from the *Taenia* species of worms. Other diagnostic procedures may be necessary when cysticercosis is suspected. Blood samples from an infected individual are collected to look for the presence of antibodies against the tapeworm larvae. In 2004, researchers isolated an antigen diagnostic for cysticercosis called GP50. In cases in which infection of the central nervous system is present, advanced imaging tests, such as **computed tomography scans** (CT) and **magnetic resonance imaging** (MRI), may be necessary to determine the exact location of the tapeworm larvae within the body.

Ultrasound imaging is also being used to diagnose tapeworm infections. Because of the recent rise in immigration and travel, clinicians in developed countries are seeing more patients with tapeworms. The World Health Organization (WHO) has developed standardized sets of ultrasound images to help doctors recognize the signs of a parasitic infection. In some cases, ultrasound allows the doctor to see the tapeworm directly.

Treatment

Effective treatment of tapeworm infections involves administering compounds that are toxic to the adult worm. Many of the early treatments were also somewhat toxic to the patient, so treatment was often quite an ordeal. Newer medications are much more easily tolerated and are highly effective in eliminating the parasite from the body. It is important to completely eliminate the head and neck regions of the tapeworm, as the entire worm can regenerate from these parts.

One treatment that has been in use since the early 1960s is niclosamide (Niclocide). This drug is poorly absorbed from the digestive tract and rapidly kills tapeworms upon exposure. It has been shown to be effective against *Taenia* species and the fish tapeworm, but treatment of the dwarf tapeworm (*H. nana*) may require a more prolonged treatment schedule. Side effects reported with niclosamide are infrequent and typically mild. When present, side effects may include nausea, abdominal discomfort, **vomiting**, diarrhea, light-headedness, and skin rash. This medication should be taken in the morning on an empty stomach. The tablets are chewed thoroughly and swallowed with water. For young children, the tablets may be pulverized and mixed with water. Patients are allowed to eat two hours after treatment. Recommended dosage is 2 g for adults and about half this for children.

Another oral medication that has been shown to be 95% effective in the treatment of tapeworm infections associated with both *Taenia* and *D. latum* species is praziquantel (Biltricide). Side effects reported for praziquantel are mild and appear to be short-lived. They include nausea, abdominal pain, **itching**, sore joints, and muscle pain.

It is recommended that follow-up stool samples be examined at one month and three months after treatment has been completed. Treatment can be considered successful if no eggs are present in several stool samples. It should be noted that the tapeworm medications do not kill the tapeworm eggs when they kill the adult worm, so the potential for infection with eggs still exists as the dead worm segments are passed. Proper personal hygiene in individuals receiving treatment will greatly reduce this potential.

Cases of neurocysticercosis, where larvae have developed in the central nervous system, may also be treated with praziquantel or albendazole. If the patient is treated promptly, damage to the central nervous system will be minimized.

Though researchers have developed several vaccines for pigs to help control neurocysticercosis, production and distribution still remain problematic.

Prognosis

When confined to the intestinal tract, tapeworms cause minimal damage to their human host. Once the diagnosis of an intestinal tapeworm infection has been made, prognosis following treatment with niclosamide or praziquantel is good. The worms can be eliminated from the intestines with oral treatment, and there are

usually no residual side effects. Serious problems from tapeworm infections occur when tapeworm eggs are consumed and the larvae localize in tissues outside the digestive tract (cysticercosis). Prompt diagnosis and treatment of this condition is necessary to prevent permanent damage to the central nervous system and other internal organs. Cysticercosis is becoming increasingly recognized as an important cause of severe neurologic disease in the United States. Untreated cases of cysticercosis have the rare potential to be life-threatening; in some cases, **liver transplantation** has been necessary to save the patient's life.

Prevention

The best way to prevent infection with tapeworms is to eliminate the exposure of livestock to the tapeworm eggs by properly disposing of human feces. The next best strategy is to thoroughly cook or freeze all meat and fish before it is eaten to prevent consumption of live tapeworm larvae in infected samples. Larval cysts in pork and beef are killed by moderate temperatures of 150°F (65°C) or if frozen for at least 12 hours. Proper cooking of freshwater fish could also eliminate the possibility of human infection with the fish tapeworm. Freezing fresh fish for 24 hours will also kill the larval form.

People who raise sheep or horses should have these animals checked regularly by a veterinarian and dewormed if necessary.

The Centers for Disease Control and Prevention (CDC) recommends that people traveling abroad should wash their hands with soap and water before handling food; should wash and peel all raw vegetables and fruits before eating; and should drink only bottled or boiled water, or carbonated drinks in cans or bottles.

Tardive dyskinesia

Definition

Tardive dyskinesia is a mostly irreversible neurological disorder of involuntary movements caused by long-term use of antipsychotic or neuroleptic drugs.

Description

Antipsychotic or neuroleptic drugs are powerful tranquilizers generally prescribed for serious psychiatric disorders, as well as neurological and gastrointestinal disorders. Some common antipsychotics are: chlorpromazine HCl (Thorazine), thioridazine HCl (Mellaril), haloperidol (Haldol), perphenazine (Trilafon), thiothixene (Navane), trifluoperazine HCl (Stelazine), and fluphenazine HCl (Permitil, Prolixin).

When these drugs are used long term, tardive dyskinesia (TD) can result. About 20% of people taking **antipsychotic drugs** for more then one year become affected by TD. The prevalence of TD tends to be highest among elderly patients and among women.

Causes and symptoms

TD usually appears after years of antipsychotic drug use, and seems to be related to the total lifetime dose of medication. The symptoms include the following:

- tongue protrusion
- grimacing
- rapid eye blinking
- lip smacking, pursing, or puckering
- rapid movement of the arms or legs
- other involuntary movements of the head, face, neck and tongue muscles

Diagnosis

The diagnosis of TD is suspected upon observation of involuntary movements of the head, neck, face, and tongue in individuals who have a history of antipsychotic drug prescription.

Treatment

There is no standard treatment for TD. The primary approach is to discontinue or minimize the use of antipsychotic drugs while attempting to treat some of the symptoms. The treatment must be individualized to the patient, because discontinuation of the antipsychotic drug(s) may not be advisable, depending on the patient's condition. In some cases, substituting another drug for the antipsychotic drug may be beneficial.

KEY TERMS

Antipsychotics—Drugs used to treat psychotic conditions such as schizophrenia or psychosis. These medications are powerful tranquilizers that all have sedating and calming effects, but their major effect is to reduce psychotic thinking and behavior.

Neuroleptics—Any of a class of drugs used to treat psychotic conditions.

Psychosis—A condition where a person's ability to recognize reality and cope with everyday life is severely affected.

Prognosis

Once TD appears in full–blown form, it can be permanent. With careful management, some symptoms may improve and even disappear with time. In less severe cases, some patients may recover from TD within three months of discontinuing the use of antipsychotic medication. Studies report that at least half of patients experience remission of major symptoms within 12 to 18 months following discontinuation of antipsychotic drugs. In some patients, however, decreasing the dose of the antipsychotic drug actually increases the symptoms of TD, while increasing the dose sometimes offers a temporary remission of the symptoms.

Prevention

TD can be prevented by early recognition and discontinuation of the antipsychotic medication if this is clinically possible. The use of antipsychotic drugs should in any case be kept to a minimum in all patients. Patients should be followed carefully to determine when the dose of the drug can be tapered off as the psychiatric condition improves. In all cases, the benefits of taking the antipsychotic medication should outweigh the risk of developing TD.

A study has shown that elderly institutionalized patients with **dementia** that were treated with risperidone had a low incidence of TD. Although further study is needed, this study shows that non-conventional neuroleptic drugs should be considered to avoid the risk of TD, particularly in elderly patients.

Cornea—The clear part of the front of the eye through which vision occurs.

Enophthalmos—A condition in which the eye falls back into the socket and inhibits proper eyelid function.

Exophthalmos—A condition in which the eyes bulge out of their sockets and inhibit proper eyelid function.

Palpebral fissure—Eyelid opening.

Sjögren's syndrome—A connective tissue disease that hinders the production of tears and other body fluids.

Tarsorrhaphy

Definition

Tarsorrhaphy is a rare procedure in which the eyelids are partially sewn together to narrow the opening.

Purpose

The eye needs the lid for protection. It also needs tears and periodic blinking to cleanse it and keep it moist. There are many conditions that impair these functions and threaten the eye, specifically the cornea, with drying. Sewing the eyelids partially together helps protect the eye until the underlying condition can be corrected.

Some of the conditions that can improve with tarsorrhaphy include:

- Paralysis or weakness of the eyelids that may prevent the eyelids from closing adequately. Bell's palsy is a nerve condition that weakens the muscles of the face, including the eyelids. It is usually temporary. Myasthenia gravis also weakens facial muscles, but it is usually treatable. A stroke can also weaken eyelids so that they do not close.
- Exophthalmos (eyes bulging out of their sockets) occurs with Graves' disease of the thyroid, and with tumors behind the eyes. If the eyes bulge out too far, the lids cannot close over them.
- Enophthalmos is a condition in which the eye falls back into the socket, making the eyelid ineffective.
- Several eye and corneal diseases cause swelling of the cornea, and require temporary added protection until the condition resolves.
- Sjögren's syndrome reduces tear flow to the point where it can endanger the cornea.
- Dendritic ulcers of the cornea caused by viruses may need to be covered with the eyelid while they heal.

Demographics

People of all ages can develop **paralysis** or corneal diseases that may benefit from tarsorrhaphy. For that reason, physicians can perform tarsorrhaphy on patients of any age. However, it is viewed as a last alternative for many patients, and is not indicated until after other treatments (e.g., patching and eye ointments) have been attempted.

Description

Ophthalmologists perform the procedure on an outpatient basis in a hospital, or sometimes in their offices.

Tarsorrhaphy is an outpatient procedure done under local anesthetic. Stitches are carefully placed at the corners of the eyelid opening (palpebral fissure) to narrow the opening. This provides the eye with improved lubrication and less air exposure. Eyeball motion can help bathe the cornea in tears when it rolls up under the lid.

Preparation

The use of eye drops and **contact lenses** to moisten and protect the eyes must be considered before tarsorrhaphy is performed. Special preparation is not necessary.

Aftercare

Patients should avoid rubbing the eye and refrain from wearing make-up until given permission from the physician. Driving should be restricted until approval from the ophthalmologist.

Pathways in the home should be cleared of obstacles, and patients should be aware of peripheral vision loss. They will need to compensate by turning their head fully when looking at an object.

An analgesic may be used to ease **pain**, but severe pain is not normal, and the physician must be alerted. Sutures will be removed in two weeks.

Eye drops or ointment may still be needed to preserve the cornea or treat accompanying disease.

Risks

Tarsorrhaphy carries few risks, but complications may include minor eyelid swelling and superficial infection.

Results

A successful tarsorrhaphy procedure protects the eye and helps it retain moisture.

Morbidity and mortality rates

This is a safe procedure. Only superficial infections have been reported.

Alternatives

Eye drops and contact lenses are widely used to treat conditions that once warranted tarsorrhaphy. The procedure is now considered a last option for treatment.

Tattoo removal

Definition

Although tattoos are considered to be permanent, it is possible to safely remove unwanted tattoos using one of several techniques.

Purpose

A growing number of people, especially the young, are getting tattoos. It is estimated that almost a quarter of all U.S. college students have at least one tattoo. However, one study found that approximately half of all people with permanent tattoos eventually attempt to have them removed.

There are many reasons—personal, cultural, and physical—why people decide to have a tattoo removed. As people age, their self-image may change such that their tattoos no longer reflect who they feel they are. As fashions change, a particular tattoo may no longer be in style. Tattoos commemorating a particular person or relationship may become inappropriate if the relationship ends—divorce is one of the most common reasons for tattoo removal. Sometimes people must have tattoos removed for a new job. Tattoos may fade or blur. Finally, some people experience allergic reactions to the ink in their tattoos or other physical complications from a tattoo.

Description

Although some tattoo shops remove tattoos, it is much safer to have them removed by a medical doctor trained in tattoo removal procedures. All tattoo removal methods are generally performed by dermatologic surgeons as an outpatient procedure in the surgeon's office or in an outpatient surgical clinic.

WWW.BOOKBAZ.IR

Tattoo removal may be accomplished with laser treatments, dermabrasion, or surgery. Tattoo removal costs anywhere between several hundred to several thousand dollars—often far more than the cost of the original tattoo. Because tattoo removal is considered an aesthetic or cosmetic procedure, it is usually not covered by medical insurance. The cost of tattoo removal depends on a number of factors, including the age of the tattoo, the number of laser treatments required to remove it, the type of **anesthesia** used for surgical removal, and whether skin grafts are required.

Other factors also affect the cost, safety, and effectiveness of tattoo removal. These factors should be carefully considered before getting a permanent tattoo:

- the type of tattoo
- the size of the tattoo
- its location on the body
- the colors and types of tattoo pigments used

Laser removal

Laser removal—also called **laser surgery**, laser therapy, laser vaporization, or laser rejuvenation—has become the most common method of tattoo removal. It is considered safer and more effective than other methods, with less risk of infection. The U.S. Food and Drug Administration (FDA) has approved several types of lasers for tattoo removal. The most common type is a handheld Q-switched laser (QSL), which delivers short pulses of very high intensity light to the outer layers of the skin. These pulses of energy quickly superheat the tattoo ink, shattering it into smaller fragments. The laser wavelength is then switched to destroy different colors until the entire tattoo has been removed. This is a slow process. Multiple treatments are usually required in order to break down the pigments into particles that are small enough to be recognized as foreign bodies by the cells of the immune system. Eventually, the particles are removed from the body by the lymphatic system. Each treatment lasts only a few minutes, but the entire process usually takes several months. There is a new tattoo ink on the market that is designed to be removable with only one or two laser treatments. Lasers usually remove tattoos without leaving a scar because the laser beam is precisely aimed to avoid damaging the skin surrounding the tattoo.

Some tattoo colors respond better than others to laser treatment. Dark blue, some lighter blues, red, and green inks tend to respond best. The wavelength of laser light is precisely tuned to each different pigment color, either by using different lasers or different settings on the same laser:

- Black tattoos on light-colored skin are the easiest to remove. Black ink responds to most wavelengths, but 1064 nanometers (nm) is most often used.
- Green ink responds best to 755 nm, although 694 nm or 650 nm can also be effective.
- Blue ink responds to 585 nm.
- Red ink responds to 532 nm.

A new type of laser, called a picosecond alexandrite laser, received FDA approval for marketing at the end of 2012. A small study suggested that it could remove tattoos with four or fewer treatments—far fewer than are generally needed with a Q-switched laser.

Dermabrasion

Dermabrasion, also known as surgical skin planing, is the traditional method for tattoo removal and may be less expensive than other methods. It is a skin-resurfacing procedure that uses a high-speed rotary instrument with an abrasive wheel or brush to sand down the surface and middle layers of the tattooed skin. This allows the tattoo ink to leach out of the body.

Surgical removal

In the past, surgical excision was the only way to remove a tattoo. Surgical tattoo removal involves physically removing the tattooed skin with a scalpel and then stitching the edges of the skin back together. It is the most invasive method of tattoo removal. However, it is the easiest and most effective method for removing some small tattoos, since it can be performed with high precision. Large tattoos are generally not good candidates for surgical removal.

Preparation

A dermatologist should be consulted before proceeding with tattoo removal. The dermatologist will explain the removal options and suggest which method is likely to be most effective. For example, some tattoo inks do not respond well to laser treatment. The doctor will probably review the patient's medical history and perform a physical exam, as well as explain the potential risks and likely outcome of the chosen removal procedure.

Prior to laser removal, it is extremely important to avoid **tanning** the area that will be treated. It is also important to avoid sun exposure for several weeks before surgical tattoo removal. Precautions include:

- using a high sun protection factor (SPF) sunblock every day and reapplying frequently when in the sun
- staying in the shade
- avoiding outdoor activities between 10 a.m. and 3 p.m.

- covering the skin with long sleeves and a hat
- wearing a bandage over the tattoo when out in the sun

Blood-thinning medications that contain **aspirin** or **nonsteroidal anti-inflammatory drugs** (NSAIDs) such as ibuprofen (Advil) should be avoided before any type of tattoo removal, since these can cause bruising or bleeding after the treatment. Medications that can cause the skin to darken (**hyperpigmentation**) should also be avoided.

Laser removal is often more painful than the original tattooing. The **pain** has been compared to being snapped repeatedly with a rubber band. A nonaspirin pain reliever such as **acetaminophen** (Tylenol) may be taken prior to the procedure. Many patients use an anesthetic cream one to two hours prior to treatment. The skin may or may not be numbed by injection with a local anesthetic. The skin is cleaned immediately before treatment.

Prior to dermabrasion, patients may be given medication to help them relax, and the tattooed area is sprayed to freeze or numb the skin. Prior to surgical tattoo removal, the treatment area is numbed by injection of a local anesthetic.

Aftercare

Following a laser treatment, the skin may be temporarily swollen and white. Blistering or bleeding is possible. The area may redden and form a scab. The wound must be cleaned gently, without scrubbing or rubbing, and kept protected from the sun. An antibacterial ointment can promote healing.

Following dermabrasion, the treated area may be sore and raw for up to ten days. An antibacterial ointment may be needed, and the area may need to be covered with a special bandage. Recovery time is usually two to three weeks. The treated area will be temporarily pink or red, with the color fading in 8 to 12 weeks. Patients must avoid the sun and regularly use sunscreen when outside for three to six months after dermabrasion, because exposure to sunlight can cause excessive scarring.

Following surgical tattoo removal, the skin may feel sunburned or tight. Pain medications or **antibiotics** may be prescribed. An ice pack and a dressing may be applied. The area must be kept clean with repeated application of antibacterial ointment, as directed by the doctor. It is usually possible to bathe or shower the day after surgery, but the treated area should not be scrubbed. A bandage or patch should be applied or, if left uncovered, sunscreen with an SPF factor of 30 or higher should be used when outside to avoid excessive scarring. The doctor also may prescribe a moisturizing cream or lotion.

Risks

Tattoo removal should never be attempted by people with certain types of **autoimmune disorders**, pigmentation problems, active **acne** or **warts**, uncontrolled or unstable diabetes, active **rosacea**, or undiagnosed lesions.

Surgery is the only method guaranteed to completely remove a tattoo, and it will leave a scar. Some scarring, infection, and skin discoloration—including temporary or permanent hyperpigmentation or lightening (hypopigmentation) of the tattooed skin—are risks with any method of tattoo removal.

Laser tattoo removal usually requires multiple treatments every few weeks, which can add up to several thousand dollars, and it may not be successful. Dermabrasion also may not completely remove the tattoo. In addition to the above risks, dermabrasion may cause redness, swelling, and bleeding. Scarring may occur if the dermabrasion penetrates too deeply into the skin. Infections are rare but possible with dermabrasion. In addition to the above risks, surgery may fail to completely remove all of the tattoo pigment, and a raised or thickened scar may develop three to six months after tattoo removal.

Home remedies

Do-it-yourself tattoo removal creams and other home treatments are dangerous and unlikely to be effective. These products are acid-based and are not approved by the FDA. They can cause serious skin irritation and other reactions. Attempting to remove tattoos at home by other methods can lead to infection, serious complications, or even death.

Results

The results of tattoo removal vary greatly, and completely removing a tattoo can be very difficult. Multiple laser treatments or dermabrasion may only succeed in lightening the tattoo. Complete removal depends on many factors, including the age and size of the tattoo and the types and colors of the inks. Sometimes more recent tattoos are more difficult to remove than older tattoos. However, sometimes older tattoos are more difficult to remove because the ink has penetrated deeper into the skin over time. Fluorescent colors are the most difficult to remove, and darker colors may be more difficult than lighter colors. Professional tattoos done with some of the newer inks and pastels may be difficult to entirely remove. Professional tattoos tend to have more uniform penetration of the deeper skin layers, which facilitates surgical removal of the inked skin to

the same depth; however, many laser treatments may be required for removal of deeply penetrating pigment. Amateur tattoos fade more easily because they have generally been applied with less ink. However, if the ink has been applied unevenly, the tattoo may be more difficult to remove completely. Although surgical removal is usually effective, it leaves a scar and may be appropriate only for small tattoos. In contrast, dermabrasion usually results in new skin that is smoother and rejuvenated in appearance.

A recent study of laser tattoo removal found that success was more likely with nonsmokers and with tattoos smaller than 12 in. (30 cm) in size. **Smoking** reduced the likelihood of successful tattoo removal with ten laser treatment sessions by 70%, possibly because smoking interferes with wound healing. Tattoos on the feet or legs were less likely to be effectively removed than tattoos elsewhere on the body. Black and red pigments were the easiest to remove. Colors such as blue or yellow were less likely to be effectively removed. Tattoos that were all black had a removal rate of 58%. Black and red tattoos had a 51% success rate after ten treatments, since black and red absorb the laser wavelengths better than other colors. Colors such as green, yellow, or blue lowered the effective removal rate by up to 80%. Intervals of eight weeks or less between laser treatments were not as effective as longer intervals between treatments.

Alternatives

An alternative to tattoo removal may be a second tattoo that covers the undesired tattoo.

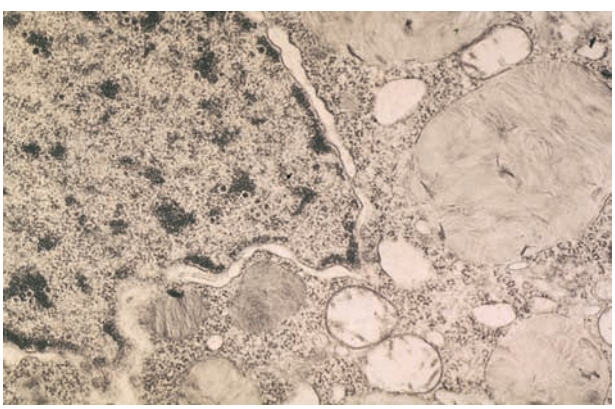
Tay-Sachs disease

Definition

Tay-Sachs disease is a genetic disorder caused by a missing enzyme that results in the accumulation of a fatty substance in the nervous system. This results in disability and death.

Description

Gangliosides are fatty substances necessary for the proper development of the brain and nerve cells (nervous system). Under normal conditions, gangliosides are continuously broken down, so that an appropriate balance is maintained. In Tay-Sachs disease, the enzyme necessary for removing excess gangliosides is missing. This allows gangliosides to accumulate throughout the brain, and is responsible for the disability associated with the disease.



Section of brain tissue from patient with Tay-Sachs disease. *(Custom Medical Stock Photo, Inc.)*

Tay-Sachs disease is particularly common among Jewish people of Eastern European and Russian (Ashkenazi) origin. About one out of every 3,600 babies born to Ashkenazi Jewish couples will have the disease. Tay-Sachs is also more common among certain French-Canadian and Cajun French families.

Causes and symptoms

Tay-Sachs is caused by a defective gene. Genes are located on chromosomes, and serve to direct specific development/processes within the body. The genetic defect in Tay-Sachs disease results in the lack of an enzyme called hexosaminidase A. Without this enzyme, gangliosides cannot be degraded. They build up within the brain, interfering with nerve functioning. Because Tay-Sachs is a recessive disorder, only people who receive two defective genes (one from the mother and one from the father) will actually have the disease. People who have only one defective gene and one normal gene are called carriers. They carry the defective gene and thus the possibility of passing the gene and/or the disease onto their offspring.

When a carrier and a non-carrier have children, none of their children will actually have Tay-Sachs. It is likely that 50% of their children will be carriers themselves. When two carriers have children, their children have a 25% chance of having normal genes, a 50% chance of being carriers of the defective gene, and a 25% chance of having two defective genes. The two defective genes cause the disease itself.

Classic Tay-Sachs disease affects infants around the age of six months. Up until this age, the baby will appear to be developing normally. When Tay-Sachs begins to show itself, the baby will stop interacting with other people and develop a staring gaze. Normal levels of noise will startle the baby to an abnormal degree. By about one year of age, the baby will have very weak, floppy muscles, and may be completely blind. The head will be quite large. Patients also present with loss of peripheral (side) vision, inability to breath and swallow, and **paralysis** as the disorder progresses. Seizures become a problem between ages one and two, and the baby usually dies by about age four.

A few variations from this classical progression of Tay-Sachs disease are possible:

- Juvenile hexosaminidase A deficiency. Symptoms appear between ages two and five; the disease progresses more slowly, with death by about 15 years.
- Chronic hexosaminidase A deficiency. Symptoms may begin around age five, or may not occur until age 20–30. The disease is milder. Speech becomes slurred. The individual may have difficulty walking due to weakness, muscle cramps, and decreased coordination of

movements. Some individuals develop mental illness. Many have changes in intellect, hearing, or vision.

Diagnosis

Examination of the eyes of a child with Tay-Sachs disease will reveal a characteristic cherry-red spot at the back of the eye (in an area called the retina). Tests to determine the presence and quantity of hexosaminidase A can be performed on the blood, specially treated skin cells, or white blood cells. A carrier will have about half of the normal level of hexosaminidase A present, while a patient with the disease will have none.

Treatment

There is no treatment for Tay-Sachs disease.

Prognosis

The prognosis for a child with classic Tay-Sachs disease is certain death. Because the chronic form of Tay-Sachs has been discovered recently, prognosis for this type of the disease is not completely known.

Prevention

Prevention involves identifying carriers of the disease and providing them with appropriate information concerning the chance of their offspring having Tay-Sachs disease. When the levels of hexosaminidase A are half the normal level, a person is a carrier of the defective gene. Blood tests of carriers reveals reduction of hexosaminidase A.

When a woman is already pregnant, tests can be performed on either the cells of the baby (aminocentesis) or the placenta (**chorionic villus sampling**) to determine whether the baby will have Tay-Sachs disease.

Technetium heart scan

Definition

The technetium heart scan is a noninvasive nuclear scan that uses a radioactive isotope called technetium to evaluate blood flow after a **heart attack**.

Purpose

The technetium heart scan is used to evaluate the heart after a heart attack. It can confirm that a patient had a heart attack when the symptoms and **pain** usually associated with a heart attack were not present; identify the size and location of the heart attack; and provide information useful in determining the patient's post-heart attack prognosis. The scan is most useful when the electrocardiogram and cardiac enzyme studies do not provide definitive results after heart surgery, for example, or when chest pain occurred more than 48 hours before the patient was examined. It is also used to evaluate the heart before and after heart surgery.

Precautions

Pregnant women and those who are **breastfeeding** should not be exposed to technetium.

Description

The technetium heart scan is a nuclear heart scan, which means that it involves the use of a radioactive isotope that targets the heart, and a radionuclide detector that traces the absorption of the radioactive isotope. The isotope is injected into a vein and absorbed by healthy tissue at a known rate during a certain time period. The radionuclide detector, in this case a gamma scintillation camera, picks up the gamma rays emitted by the isotope.

The technetium heart scan uses technetium Tc-99m stannous pyrophosphate (usually called technetium), a mildly radioactive isotope that binds to **calcium**. After a heart attack, tiny calcium deposits appear on diseased heart valves and damaged heart tissue. These deposits appear within 12 hours of the heart attack. They are generally seen two to three days after the heart attack and are usually gone within one to two weeks. In some patients, they can be seen for several months.

After the technetium is injected into a blood vessel in the arm, it accumulates in heart tissue that has been damaged, leaving "hot spots" that can be detected by the scintillation camera. The technetium heart scan provides better image quality than commonly used radioactive agents such as thallium, because it has a shorter half-life and can be given in larger doses.

During the test, the patient lies motionless on the test table. Electrocardiogram electrodes are placed on the patient's body for continuous monitoring during the test. The test table is rotated so that different views of the heart can be scanned. The camera, which looks like an x-ray machine and is suspended above the table, moves back and forth over the patient. It displays a series of images of technetium's movement through the heart and records them on a computer for later analysis.

The test is usually performed at least 12 hours after a suspected heart attack, but it can also be done during triage of a patient who goes to a hospital emergency room with chest pain but does not appear to have had a heart attack. Recent clinical studies demonstrate that technetium heart scans are very accurate in detecting heart attacks while the patient is experiencing chest pain. They are far more accurate than electrocardiogram findings.

The technetium heart scan is usually performed in a hospital's nuclear medicine department but it can be done at the patient's bedside during a heart attack if the equipment is available. The scan is done two to three hours after the technetium is injected. Scans are usually done with the patient in several positions, with each scan taking 10 minutes. The entire test takes about 30 minutes to an hour. The scan is usually repeated over several weeks to determine if any further damage has been done to the heart. The test is also called technetium 99m pyrophosphate scintigraphy, hot-spot myocardial imaging, infarct avid imaging, or myocardial infarction scan.

The technetium heart scan is not dangerous. The technetium is completely gone from the body within a few days of the test. The scan itself exposes the patient to about the same amount of radiation as a chest x ray. The patient can resume normal activities immediately after the test.

Preparation

Two to three hours before the scan, technetium is injected into a vein in the patient's forearm.

Results

If the technetium heart scan is normal, no technetium will show up in the heart.

KEY TERMS

Electrocardiogram—A test in which electronic sensors called electrodes are placed on the body to record the heart's electrical activities.

Noninvasive—A procedure that does not penetrate the body.

Radioactive isotope—One of two or more atoms with the same number of protons but a different number of neutrons with a nuclear composition. In nuclear scanning, radioactive isotopes are used as a diagnostic agent.

Technetium—A radioactive isotope frequently used in radionuclide scanning of the heart and other organs. It is produced during nuclear fission reactions.

Abnormal results

In an abnormal technetium heart scan, hot spots reveal damage to the heart. The larger the hot spots, the poorer the patient's prognosis.

Teen health

Definition

Teen health entails how to prevent, detect, and treat problems with mental and physical health in teenagers, that is, young people aged 10–19, and promote their wellbeing.

Description

More than 42 million teens live in the United States. Also called adolescent health, teen health is an approach to helping young people live happy, productive, and healthy lives. Teen health also promotes healthy habits in teens that can prevent diseases as

WWW.BOOKBAZ.IR

adolescents become adults and improve their quality of life for years to come.

Children develop rapidly during adolescence, and their biological development, or the changes in their bodies' sizes, shapes, and functions, usually happens more quickly than their emotional development. Most of the physical development of teens occurs when they reach **puberty**. At this time, boys begin to have more muscle, and girls develop breasts and a more curvy shape. Social development must occur during the teen years, when a child's life begins to revolve less around the family and more around friends and activities beyond the home. Teens often enter periods when they rebel against authority or experience depression and **anxiety** as they go through emotional development and become more aware of themselves. Parts of the adolescent brain develop more rapidly than other areas, which explains some of the problems teens have with reasoning, moods, and controlling impulses. It takes a unique approach and specialized caregivers to help promote and improve teen health.

Teen health comprises many different areas, including physical health and areas of mental health. Adolescence is a time in which teens must transition from childhood and dependence on their parents to adulthood and being independent. They also must learn to adopt healthy lifestyles, deal with peer pressure, and address the many physical changes that accompany their growth.

As a result of the many changes that occur in teens' lives, brains, and bodies, teen health typically involves several key areas:

- physical health and diet, which is important because teen bodies can grow rapidly and many adolescents participate in sports. Concerns include drinking too many sodas or energy drinks, obesity, acne, eating disorders, and getting enough sleep and exercise.
- mental health, as teens learn to make good decisions even when under pressure from peers. Teens usually have mood swings, but as many as 20% of adolescents have a mental health disorder such as depression, bipolar disorder, or anxiety disorder. Teens must learn to cope with many social pressures as they move to adulthood.
- substance abuse, the use of alcohol and drugs among teens. In addition, teen smoking is a major health concern because of its long-term effects.
- relationships, which is how teens come to interact with their parents, peers, authority figures, friends, and partners. These relationships help form the teen's identity as the teen matures, and relationships affect their future life.
- safety concerns, such as preventing risky behaviors that cause injury to the teen or others, preventing the teen from getting into trouble at school and with the law, and preventing teen pregnancy. Teens want to look good but must understand the health consequences of tanning or possible infections may come from getting tattoos or piercings.
- dealing with chronic illness, which is a problem for as many as 17% of American teens. Some adolescents develop types of cancer that are common for their age group or have chronic illnesses such as type 1 diabetes or juvenile arthritis. It is especially difficult for teens with a chronic disease to face the pressures of adolescence and manage their health, often when they must miss school or activities that many teens enjoy because of doctor appointments, illness, or procedures. These teens must learn to manage their illness in addition to everyday health and prevention.

Purpose

Although most teens are healthy, some die at young ages because of accidents, violence, **suicide**, or other preventable problems. Promoting teen health can help to prevent some of these deaths and improve the lives of teens. In addition, many adult diseases are caused or made worse by behaviors that begin in adolescence. For example, many people who smoke cigarettes begin **smoking** during their teen years. Efforts to stop teen smoking could help prevent future lung disease and cancer in adults. By contrast, teens who adopt healthy **exercise** and eating habits set the stage for healthy behaviors as adults. Many policymakers around the world believe that investing in improving the health of teens can improve the future economies and overall societies in their countries.

Preparation

Parents can begin to prepare teens for healthy behaviors by reinforcing healthy eating and exercise habits, smart decisions about peers and other behaviors, and helping their teens develop positive self-esteem. Teens also should continue to have vaccines as recommended by their doctors:

- The human papillomavirus (HPV) vaccine is recommended for boys and girls at age 11 or 12 years to protect against HPV and its health consequences, including some forms of cancer.
- The tetanus-diphtheria-acellar pertussis (Tdap) vaccine is a booster shot to protect preteens and teens from the same diseases they received vaccines for when younger in case the vaccine's effectiveness wears off.

KEY TERMS

Human papillomavirus (HPV)—A sexually transmitted infection that can cause several types of cancer in people who become infected with the virus.

Puberty—The time of normal development when a child's body matures to be more like an adult body. It involves development of sexual hormones and sexual organs that enable reproduction.

- A meningococcal vaccine can protect against meningococcal disease, or meningitis, an inflammation of the lining around the brain and spinal cord. Teens are at especially high risk for the disease.
- A flu shot each year should help protect against flu strains.

Aftercare

When a child reaches the teen years, parents and teens should make a decision about healthcare, such as whether the teen is comfortable continuing to receive care from a pediatrician. In general, pediatricians can see patients through age 18. Girls also may need to begin seeing a doctor who specializes in female reproductive health, between the ages of 13 and 15. Many teens need referral to dermatologists for skin care, to specialists for chronic diseases, or to mental health professionals.

As a teen enters late adolescence, parents should begin preparing the teen for adulthood and independence. This includes teaching the teen to drive safely, encouraging the teen to find a job, preparing for college or other training following high school, and suggesting ways to manage money and health. Parents can serve as excellent role models for a teen's health by showing teens responsible behavior regarding drinking, driving, exercise, and **nutrition**.

Risks

In the United States, at least 18% of adolescents are obese. Nearly 13% of teens use alcohol. Injury, homicide, and suicide rank as the highest causes of death among American teens. Nearly 10% have no health insurance and almost 5% have no regular source of medical care. Internationally, most teens die from injuries on roadways, HIV, suicide, respiratory infections, and violence. In fall of 2014, the World Health Organization (WHO) stated that many countries are placing greater emphasis on adolescent health, especially on sexual and reproductive health and HIV prevention. Countries also are attempting to train more people in teen health and creating new programs to serve adolescents.

Teen relationship abuse

Definition

Teen relationship **abuse** is any kind of physical, sexual, or emotional abuse of a teen by an individual with whom they have a romantic relationship.

Description

Teen relationship abuse is physical, sexual, or emotional abuse that is perpetrated against a teen by his or her romantic partner. Relationship abuse happens to both males and females of any dating age in both heterosexual and homosexual relationships.

WWW.BOOKBAZ.IR

Physical abuse can come in many forms, including hitting, kicking, pushing, pulling hair, and slapping. It can also include burning, forcible restriction of movement, **choking**, or any other instance in which **pain** or discomfort is caused purposefully. In some cases, the physical abuse will leave lasting marks or cause serious or permanent damage. In other cases, the abuser is careful to harm only areas that remain covered, or to abuse in such a way that little or no physical indications remain. Teens in abusive relationships may also attempt to cover up or deny physical signs of abuse, or try to explain away any visible marks.

Sexual abuse includes any type of unwanted sexual advance. Just because an individual is in a romantic relationship, it does not give him or her the right to expect, demand, or force any kind of sexual activities. Even sexual activities that were previously undertaken consensually can be abusive if one teen indicates that he or she does not want to engage in such activities again. Engaging in unprotected sex without the other partner's consent is also considered a form of sexual abuse.

Emotional abuse is somewhat more difficult to define and detect than physical or sexual abuse. While some fighting or disagreement is common in any relationship, an individual who is emotionally abusive will frequently say hurtful, unkind things, put the other person down, or be extremely controlling. Common forms of emotional abuse occur when the abuser is extremely jealous, demanding to know what his or her romantic partner is doing and with whom at all times, trying to control clothing, or other choices, and/or making the teen feel controlled, powerless, and afraid.

Demographics

Teen relationship abuse is very common. According to the Centers for Disease Control and Prevention (CDC), about 9% of high school students report having been physically harmed by a romantic partner in the past year. Males and females were about as equally likely to report having been physically abused. All ages of students who were dating reported about the same levels of physical relationship abuse. When emotional and sexual abuse is included, the rate of relationship abuse is much higher, with as many as one in three teens reporting some kind of abuse. Being a victim of abuse often starts during the teen years and can be a very difficult cycle to break. Adults who were victims of abuse often experienced their first relationship abuse during their teen years, with 15% of men, and 22% of women who were victimized as adults reporting that their first experience of abuse occurred between the ages of 11 and 17.

Causes and symptoms

There is nothing a teen can do to cause someone to abuse him or her. Abuse is never the fault of the victim, although it is common that the abuser attempts to convince the victim that he or she has done something to cause or deserve the abuse.

It is not clear why some individuals have healthy, nurturing relationships and other become abusive. Anger or control issues, a family history of violence, alcohol use, and drug use are all believed to be contributors to becoming an abuser.

Abuse can be physical, emotional, or sexual. Physical abuse is often the easiest to detect, as there can be visible effects of the abuse such as broken bones, **scars**, or **bruises**. Emotional and sexual abuse can be harder to detect, as there are less likely to be visible signs of the abuse. Even someone who is being physically abused may not have any physical symptoms, as the abuser may hurt him or her in areas that are not generally uncovered, such as the thigh or stomach, or may hurt the individual in ways that are less likely to leave marks.

The most common symptoms of teen relationship abuse are not physical. Some common signs that a teen may be in an abusive relationship include:

- sudden drop in school performance or attendance.
- no longer participating in activities that used to interest him or her such as after school activities or sports.
- beginning to use drugs or alcohol, or increasing usage.
- reduced interest in spending time with friends or family.
- offering confusing or contradictory reasons for not engaging in activities he or she used to enjoy, or refusing to offer any reason.
- making excuses for his or her significant other's behavior.
- seeming more stressed, tired, or on edge.
- frequently worrying about what his or her significant other will say about their activities, dress, or other choices.

While none of these items are clear markers by themselves, they may be signs of an abusive relationship. Pulling away from friends and family is one of the most common signs, which can make it even more difficult for loved ones to discover the truth about the abusive relationship and offer help.

Teens who are in an abusive relationship often experience a wide variety of negative physical and

emotional problems in addition to those directly inflicted by the abuser. These can include:

- depression
- fear
- shame or guilt
- problems trusting others
- decreased appetite and weight loss
- anxiety
- headaches
- loss of interest in previously enjoyable activities

Diagnosis

Most instances of teen relationship abuse are diagnosed because the teen in the relationship reaches out or a friend or classmate brings the issue to the attention of a teacher or other trusted adult. Asking teens about their significant others and watching for signs of psychical, sexual, or emotional abuse can help identify relationships in which abuse may be occurring. Teachers, doctors, coaches, and other adults who are likely to be trusted by teens should be careful to notice any signs that a teen may be experiencing relationship abuse, and should never disbelieve or ignore any teen who reaches out for help.

To determine if a relationship is abusive a doctor, counselor, or other trained adult will ask the teen questions about the relationship, and may examine the teen for signs of physical or sexual abuse.

Treatment

There are three steps to treating a teen who is in an abusive relationship. First, immediate physical or emotional needs must be met, and any physical injuries should be treated. After the immediate safety of the teen is assured, a plan for how he or she can end the relationship should be developed in conjunction with trusted adults or friends. Ending an abusive relationship can be dangerous. The relationship should be ended in a way that ensures the teen's safety, such as in a public place or via email. As the abuser may become angry and seek out the teen, ensuring the teen's ongoing safety should be a priority. Parents and other trusted adults can help by ensuring that the teen and the abuser will not have to spend time together, such as in a class, and that the abuser does not have access to the teen at home or during school activities.

Even once the abuse has stopped, the relationship has ended, and any physical injuries are healed, treatment is not over. Abuse can have a long-lasting impact, and teens who have experienced abuse should be screened for psychological and emotional problems such as depression and **anxiety**. Treatment for these types of problem may require months or years.

KEY TERMS

Substance abuse disorder—Disorder that is characterized by an individual's need for more of a drug or alcohol than intended, an inability to stop using by choice, and an ongoing difficulty in recovering from the effects of the substance.

The abuser in an abusive relationship also deserves treatment. However, such treatment should not encourage abused individuals to continue or renew their relationship with the abuser. Treatment of any underlying alcohol or substance abuse disorders, psychological counseling or therapy, and **anger management** training can help former abusers work towards having healthy, abuse-free relationships.

Prognosis

The prognosis for teens who successfully leave abusive relationships is generally very good. With support from friends, parents, and other adults in their lives, most teens can go on to have healthy self-esteem and healthy relationships. It is important for any physical or emotional issues caused by the abuse to be treated, and seeing a therapist may help the teen better work-through any lingering issues of trust, self-respect, and fear. An abusive relationship can cause serious damage to mental and physical health, but with treatment, support, and time, the teen can emerge healthy and strong.

Teeth whitening

Definition

Teeth whitening is the process of using bleach or other materials to make teeth look whiter. The materials remove stains or other discoloration from the tooth surface.

Purpose

Teeth whitening is a cosmetic treatment done to improve the appearance of teeth. Teeth are whitened to remove the effects of coffee, cigarettes, and other substances that permanently stain or discolor teeth. Medications such as **antibiotics** like tetracycline may discolor teeth. Fluorosis, a condition caused by absorbing too much fluoride, could affect tooth color. **Aging** also causes teeth to loose their bright color.

Precautions

Teeth whitening is not safe or effective for everyone, so a person should have a dental exam before starting treatment. The dentist can advise the patient about the most appropriate procedure. The oral health professional will also discuss the expected results of treatment. Patients may expect yellow or gray teeth to be replaced with a bright, white color. However, whitening may not work well on some stain colors.

The importance of a check-up

Whitening may not be recommended for people with gum disease, receding gums, or sensitive teeth. The dentist may advise against certain treatments if the enamel is worn. Enamel is the outer layer of the tooth. There is no enamel on an exposed tooth root, so the root cannot be whitened.

In addition, cavities must be filled before treatment begins. Otherwise, the patient could experience additional mouth sensitivity when treatment material comes into contact with decay or the tooth interior.

When whitening is not recommended

Women who are pregnant and nursing should avoid any whitening treatment except for toothpaste. Oral healthcare professionals advise that other treatments could contain levels of peroxide that are potentially dangerous to the child. Although no connections have been made between these treatments and harm to the child's health, mothers are urged to take preventive action and delay whitening treatment.

Teenagers should not have their teeth bleached until they are between 14 and 16 years old. In a younger child, the nerve of the tooth called the pulp chamber has not fully developed. Whitening at this point could irritate the pulp and cause sensitivity.

People who are allergic to peroxide should not be treated with this whitening agent.

Cautions about tooth color

Treatments such as bleaching are most effective on yellowish stains, according to the American Dental Association (ADA). Teeth with brown stains may not bleach as well, and the treatment is even less effective on gray-stained teeth.

Furthermore, bleaching will not change the color of tooth-colored fillings, dentures, crowns, porcelain restorations, bonding, or other material used to restore or replace a tooth. If bleaching is done, the newly whitened teeth will stand out in contrast to fillings or other modifications.

Description

Teeth are whitened by the use of bleach or other material. The treatment may be done in the dental office, at home with guidance from a dentist, or at home with the use of over-the-counter products. Tools for self-treatment include bleaching trays, gels or strips that are applied to the teeth, and toothpaste.

Whitening treatments are cosmetic procedures, and are usually not covered by dental insurance.

Products used by oral health professionals such and those sold over the counter may have the ADA Seal of Acceptance. This endorsement indicates that products carrying the seal have met the ADA's criteria for safety

and effectiveness. Those standards are based on the patient following directions when the product is used.

The ADA evaluation program is voluntary. That means manufacturers are not required to submit products for review. As a result, the lack of a seal may not indicate that the product is unsafe. However, products on the accepted list have the ADA endorsement, and the association may take positions on certain unevaluated procedures such as laser treatment.

Dental office treatment

The whitening treatment provided by dentists is known as chairside bleaching, in-office bleaching, or power bleaching. The dentist first protects the patient's gums and tissue by applying a protective gel or a rubber shield. The dentist than applies a whitening solution on the teeth.

The whitening solution contains hydrogen peroxide, which is a bleaching agent that could change the tooth color. The bleach is used to remove surface (extrinsic) and deeper (intrinsic) stains. Professionally applied whiteners, those solutions used by dentists, usually contain hydrogen peroxide. This bleaching agent comes in concentrations ranging from 15% to 35%. All solutions with the ADA Seal had a 35% concentration of hydrogen peroxide.

After the gel is applied, a light may be shined on the teeth to accelerate the whitening agent. Some agents are enhanced by lasers. However, no treatments requiring lasers were on the ADA list of accepted products as of 2014. Although lasers may be safe, the association had not seen published, peer-reviewed data on the safety and effectiveness of laser whitening.

Chairside bleaching treatment may last from thirty minutes to an hour, according to the ADA. In addition, patients may need to return for additional treatments. The cost of treatment for the whole mouth can cost from $500–1,000. Factors affecting cost include the patient's location and the number of treatments needed. At the high end of the range is laser treatment, which could cost $1,000 or more.

Dentist-supervised treatment

Supervised treatment combines visits to the dentist with treatment at home. The procedure is also called tray bleaching or nightguard bleaching because the patient wears a tray on the teeth that protects the gums from the whitening solution.

For this treatment, the dentist takes an impression of the patient's teeth and makes a mouthpiece tray, or mouthguard, that will fit over the teeth. The dentist dispenses a whitening gel that the patient will place in the customized mouthguard.

The gel usually contains carbamide peroxide, which comes in concentrations of 10%, 16%, and 22%. Products with the ADA Seal have a 10% concentration. That amount is the equivalent of an approximately 3% concentration of hydrogen peroxide. The ADA endorsement applies only to home systems dispensed by dentists. The association's Seal reflects the importance of consulting with a dentist before undergoing treatment at home, according to the ADA.

The dentist will set up a schedule for wearing the mouthguard. Wearing times vary by product. A patient may wear the piece overnight for one to two weeks. For other systems, the patient wears the mouthguard for a set amount of time twice a day. This treatment usually lasts two weeks.

During supervised treatment, the dentist generally schedules appointments to monitor the patient's progress. In addition to checking the whitening process, the dentist may examine the fit of the mouthguard and look for signs of gum irritation.

Supervised home bleaching of the whole mouth costs $300–600.

Over-the-counter (OTC) products

In-home treatments that can be purchased over-the-counter include products that use bleach in mouthguard trays as well as strips and gels. The bleaching agent is usually carbamide peroxide, which is not as strong as the hydrogen peroxide found in solutions that are used in chairside bleaching and supervised home treatment.

OTC treatments range in price from $20–150. Treatment lasts 14 days on average. Another treatment is the use of whitening toothpaste, a product that does not contain bleach.

TRAY TREATMENT. Mouthguard treatment kits can be bought in stores and over the Internet. The tray kits involve the use of a mouthguard and gel. While similar to dentist-supervised home treatment, the patient does not use a customized tray specifically for her or his mouth. Some kits have mouthguards that patients can mold to their teeth. However, the patient relies on the generic instructions provided by the manufacturer.

GELS AND WHITENING STRIPS. Gels are applied directly to the teeth. Whitening strips are thin, clear strips coated with a peroxide-based gel. The strips are applied to the teeth and worn for 30 minutes twice a day. Treatment time varies by product and generally lasts 5–14 days.

KEY TERMS

Enamel—The hard, white, outer layer of the tooth.

Fluoride—A compound believed to combat cavities in teeth.

Peroxide—A bleaching agent that is a compound consisting of two atoms of oxygen connected by a single bond.

WHITENING TOOTHPASTES. Whitening toothpastes do not contain bleach. Instead mild abrasives remove surface stains, but do not change tooth color. Products with the ADA Seal contain special chemicals or polishing agents that remove stains. A tube of whitening toothpaste costs about $5.

Preparation

The ADA advises people to consult with a dentist before beginning any teeth whitening treatment. The dentist can review the patient's oral **health history** and discuss the appropriate treatment. If necessary, the dentist will fill cavities.

Aftercare

During supervised at-home treatment, the dentist may schedule appointments to check on the progress of whitening, side effects, and the tray fit.

After treatment is completed, people need to be aware that **smoking** will cause teeth to discolor. Beverages with **caffeine** should be consumed with a straw to reduce the effects of staining. Another preventive action is brushing the teeth after drinking or eating foods that cause stains.

Risks

Teeth-whitening may cause sensitivity to hot and cold food and beverages. This is a temporary side effect that usually ends when treatment is completed. Some patients also experience gum irritation if the tray does not fit properly.

Results

Dentists use a stronger bleaching agent than that found in commercial products, so in-office whitening treatment produces a more dramatic effect on teeth with yellow stains. Over-the-counter products with bleach provide some change in the tooth color, and whitening toothpaste works only on surface stains.

Bleaching does not leave teeth permanently white. Whitening can last from six months to a year. Sometimes teeth stay white even longer. However, smoking or consumption of food and beverages that stain can cause discoloration within one month.

Teething

Definition

Teething is the emergence (eruption) through the gums of a baby's first or primary teeth.

Demographics

Every baby is different when it comes to teething. The timing of primary tooth eruption can vary by two or more years, but teething generally begins 4–8 months after birth. Some babies begin teething as early as three months and other do not begin until long past eight months. Rarely, children are born with one or two teeth—called natal teeth—or have neonatal teeth emerge during the first month of life.

Dental development in girls generally proceeds ahead of that in boys, often by as much as 6%. However, most children have all of their 20 primary teeth by age three. It is extremely rare for children to not have primary teeth.

Description

The 20 primary (baby) teeth are usually forming in the gums at birth. By 12–15 months of age, all of the primary teeth within the gums have formed crowns. Primary teeth usually erupt in pairs—one each on the right and left sides of the mouth. In general, the pairs alternate between the lower and upper jaws and proceed from front to back. From the age of six months on, children get four new teeth about every four months. The order of tooth eruption, as well as the timing, can vary.

Primary teeth usually erupt in the following order:

- the two lower central incisors or front teeth at 6–10 months of age
- the two upper central incisors four to eight weeks later, at 8–12 months
- the two upper lateral or side incisors, on each side of the central incisors, at 9–13 months
- the two lower lateral incisors about one month later, at 10–16 months of age
- the two upper first molars, for grinding food, at 13–19 months
- the two lower first molars at 14–18 months
- the two upper canines or cuspids—the pointy eye-teeth between the lateral incisors and the first molars—at 16–22 months
- the two lower canines or cuspids at 17–23 months
- the two lower second or lateral molars at 23–31 months
- the two upper second or lateral molars at 25–33 months

Most children have all 20 primary teeth by 2.5–3 years of age. These are known as the deciduous teeth because they eventually fall out and are replaced by the 32 permanent adult or secondary teeth, which begin to form within the jaw shortly before or at birth. The first permanent teeth—the six-year-molars or first permanent molars—erupt behind each of the four second baby molars, usually between the ages of five and six.

Children begin losing their primary teeth at about age six, after the permanent front teeth are almost completely formed beneath the gums. The pressure of the developing permanent teeth causes the roots of the primary teeth to dissolve. Without their anchor in the jaw, the baby teeth loosen and eventually fall out, usually beginning with the lower front teeth. The earlier the baby teeth come in, the earlier they will fall out. Most children have lost all of their baby teeth by age 13.

Risk factors

The age and rapidity at which babies undergo teething is determined primarily by hereditary factors. Various medical conditions, such as **Down syndrome**, can cause delays in teething.

Causes and symptoms

Teething is caused by the crowns of the developing primary teeth erupting through the gum tissue. For some children, teething is painless and passes almost unnoticed. For others, teething can cause considerable discomfort due to the pressure exerted on the periodontal membrane by the erupting tooth. The eruption of the large molars, in particular, can be painful. Periods of discomfort and irritability may be very brief or may last for weeks. In some cases, teething can be a

WWW.BOOKBAZ.IR

significant source of **stress** for both parents and child. Teething does not interfere with **breastfeeding**.

Symptoms of teething usually begin 3–5 days before a tooth shows and disappear as soon as the tooth has broken through the skin of the gum. Symptoms of teething may include:

- tender, red, swollen gums at the site of the erupting tooth
- flushed cheeks
- congestion
- dribbling or drooling from the mouth
- rubbing of the gums
- thumb sucking
- the desire to chew or bite down hard on various objects
- fussiness and irritability
- restlessness
- loss of appetite or refusal of food
- sleep disruptions
- excessive crying
- a slight fever from inflamed gums, no higher than 101°F (38.3°C)

Teething can sometimes cause earaches. It does not cause other childhood symptoms such as significant **fever**, **diarrhea**, or **vomiting**.

Diagnosis

Examination

Teething does not usually require medical consultation. However, if teething appears to cause prolonged or excessive irritability, severe **pain**, or pus, gum swelling, or excessive redness, a pediatrician or dentist should be consulted. It is usually recommended that children first visit a pediatric dentist within six months of their first tooth eruption or by one year of age. By the age of two children should be examined by a dentist at least twice per year.

Tests

There are no specific tests for teething.

Procedures

If the eruption of the primary teeth appears to be preceding abnormally, the dentist may order x rays of the developing teeth inside the gums.

KEY TERMS

Canine; cuspid—Eyetooth; the conical, pointed tooth between the lateral incisor and the first primary molar or permanent premolar.

Crown—The part of the tooth above the gum.

Deciduous teeth—The primary, baby, or milk teeth that fall out and are replaced by permanent teeth.

Eruption—The emergence of a tooth through the gum.

Incisors—The eight front cutting teeth–four in the lower jaw and four in the upper jaw, located between the canines.

Molars—The teeth behind the primary canines or permanent premolars, with large crowns and broad chewing surfaces for grinding food.

Treatment

Traditional treatments for teething include massaging the baby's gums and using cold teething rings to relieve discomfort. Natal or neonatal teeth are often mobile and poorly formed. Although these are primary teeth, rather than extra teeth, they may have to be removed if they interfere with feeding, irritate the tongue or lips, or are likely to come loose and cause **choking**. Sometimes children develop an extra primary tooth. This can interfere with the eruption of the permanent tooth beneath and must be extracted.

Drugs

Acetaminophen (Infant Tylenol or others) can help relieve discomfort in teething babies and young children. Acetaminophen should only be administered after consultation with a pediatrician. It is very important to choose an over-the-counter (OTC) acetaminophen–containing product that is manufactured specifically for the child's age and to carefully follow all dosing instructions. Children should never be given **aspirin** because of the rare but serious risk of Reye's syndrome. Aspirin should never be held against a tooth; nor should alcohol be rubbed into a baby's gums.

OTC teething gels contain a topical anesthetic, such as benzocaine or lidocaine, that temporarily numbs the gums and relieves discomfort. Again, it is important to consult a pediatrician and to carefully follow the manufacturer's instructions. These gels can be harmful if used improperly, can cause reactions in

some babies, and, if swallowed, can numb the throat and interfere with the gag reflex. Teething powders should never be used.

Alternatives

Chamomile (*Matricaria recutita*, *Chamaemelum nobile*) is widely used as an herbal remedy for teething discomfort.

Home remedies

Teething symptoms are generally treated at home. Drool from a teething baby should be wiped away frequently to prevent **rashes** around the mouth and face and on the chest.

There are various types of teething aids that babies can chew on. In addition to relieving discomfort and massaging the gums, these may help speed tooth eruption. Frozen teething toys numb the gums and reduce swelling, but should not be left in the baby's mouth for more than one minute at a time. They should be removed from the freezer before becoming rock hard because they can bruise swollen gums. Teething aids must be large enough that they cannot fit completely in the mouth and be swallowed. They must be sturdy enough that they will not break into pieces. Rubber teething rings with liquid inside should be avoided because they can break and leak. Teething rings should never be tied around a baby's neck because of the risk of strangulation.

There are various other home remedies for teething:

- The baby's gums can be massaged with a clean finger or cool wet washcloth.
- The baby can chew on a wet washcloth that has been in the freezer for 30 minutes. It should be washed after each use.
- Older children can chew on ice, cold food such as an apple or frozen banana, or hard biscuits.
- The sore area should be kept clean but not brushed hard.
- The sore area may be rinsed often with saltwater (one teaspoon of salt per cup of warm water).

Prognosis

Most children teethe with a minimum of discomfort. The subsequent eruption of permanent teeth is generally pain-free.

Prevention

Daily dental care should begin even before the eruption of the first tooth. Although children lose their primary teeth, dental decay can hasten tooth loss. This can leave gaps before the permanent teeth emerge and cause the primary teeth to crowd in to fill the gaps, leading to crooked permanent teeth. Decay also can spread to the permanent teeth forming in the gums.

To help prevent decay and promote healthy gums prior to the eruption of primary teeth, an infant's mouth should be wiped with a damp cloth after breastfeeding and the baby's gums should be wiped at least once or twice daily with a clean, damp cloth or gauze.

Erupting teeth should be wiped with a damp cloth. All tooth surfaces and the gum line should be thoroughly cleaned using a soft, nylon-bristled, infant toothbrush. Once all of the primary teeth have erupted, the teeth should be brushed at least twice per day, especially after meals.

Toothbrushes should be replaced every three months or when they become worn or frayed. Toothpaste should not be used until the child is able to spit it out, usually at about age three, and then only about a pea-sized amount should be used. Toothpaste should contain fluoride, but children should never be allowed to swallow fluoride toothpaste. Although children may start brushing their own teeth, the parent should remain the primary tooth brusher until the child is about five years of age. Flossing should begin once two teeth begin to touch.

In addition:

- Babies should never be allowed to comfort themselves or fall asleep with a bottle or sippy cup containing anything but water. Milk or juice can collect in the baby's mouth and cause plaque and tooth decay.
- Children should be given juice or flavored milk products only with meals.
- Pacifiers should never be sweetened with honey or other substances.
- Children should be offered fresh fruit and vegetable snacks rather than sugar.
- Parents should practice good oral hygiene and regular dental visits as examples to their children.

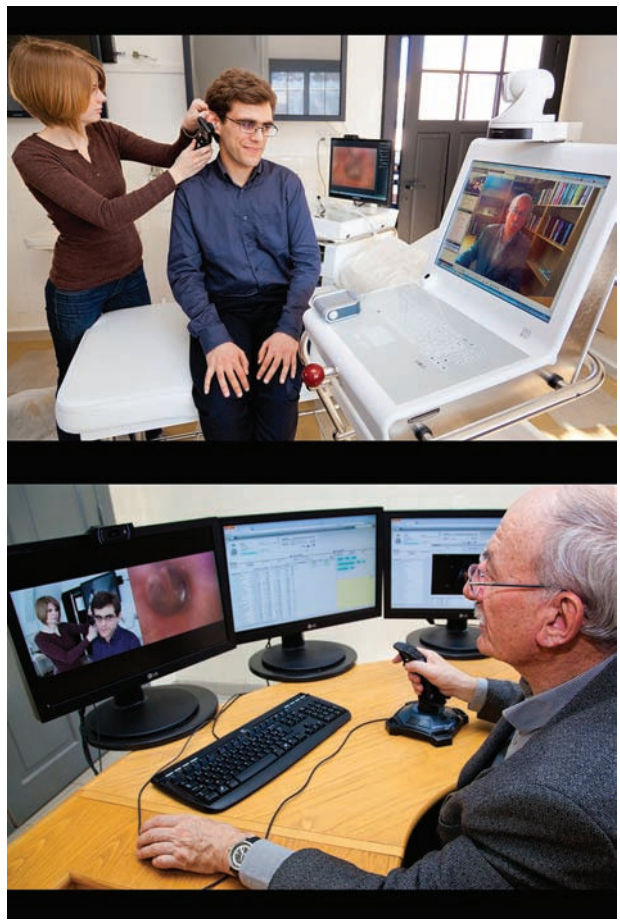
Telehealth

Definition

Telehealth, as defined by the federal Health Resources and Services Administration (HRSA), is "the use of electronic information and telecommunications technologies to support long-distance clinical healthcare, patient and professional health-related education, **public health** and health administration." It is not a separate medical specialty but rather described as the application of information technology (IT) to all fields of healthcare.

Some organizations, like the American Telemedicine Association (ATA), use the terms *telehealth* and *telemedicine* interchangeably: "telemedicine is the use of medical information exchanged from one site to another via electronic communications to improve a patient's clinical health status. Telemedicine includes a growing variety of applications and services using two-way video, e-mail, smart phones, wireless tools, and other forms of telecommunications technology." Other institutions, like HRSA, prefer to restrict *telemedicine* to the provision of clinical services via telecommunication and use *telehealth* as a broader term that includes such nonclinical health-related activities as continuing medical education (CME), telementoring among healthcare professionals, and hospital administration.



This system of remote viewing was developed by the consortium Hopi, Toshiba and NEOLINKS under the coordination of Professor Jacques Cinqualbre in Strasbourg, France. *(Garo / Phanie / Science Source)*

Description

Telehealth can be conducted by a range of telecommunications devices, from standard telephones and desktop computers to mobile smartphones, tablet computers, and videoconferencing equipment. Telehealth has two basic modes, which are known as "real-time" and "store-and-forward" telehealth, respectively. Real-time telehealth, also called "synchronous telehealth," allows instantaneous long-distance interaction between a patient and healthcare provider, or between two healthcare professionals. Videoconferencing is a common form of real-time telehealth. It can be used to perform physical examinations at a distance with the help of peripheral devices attached

to the videoconferencing equipment, as well as to conduct **psychotherapy**, continuing medical education for health professionals, and telementoring. The site where the patient (or health professional receiving training) is located is called the "originating site." The originating site may be the patient's home, a hospital, a rural healthcare clinic, or some other federally qualified health center. The site where the medical professional is providing the care or instruction is called the "distant site" or the "hub site."

Store-and-forward telehealth, also called "asynchronous telehealth," utilizes communications technology to record images as well as audio and video transmissions. These data can be stored on the client computer and then transmitted (forwarded) at a later time to another clinic or laboratory for purposes of diagnosis or analysis. Store-and-forward telehealth is increasingly used in such specialties as dermatology, **radiology**, and pathology, in which diagnosis is made in large part on the basis of images, and which do not require an immediate evaluation and reply.

A newer mode of telehealth is m-health (also spelled mHealth), or mobile health. M-health involves the use of cell phones, tablet computers, and other mobile devices. M-health can be used for either real-time or store-and-forward telehealth. M-health is a promising form of healthcare delivery in developing countries because of its usefulness in tracking diseases and collecting patient data as well as improving patient access to healthcare in remote areas in these countries. As of 2014, tens of thousands of healthcare-related applications (apps) are available for mobile devices. These include everything from health monitoring apps that check heart rate to health apps that monitor the time an individual spends participating in physical activity.

Origins

Telemedicine and telehealth have been in use in the United States and Canada since the 1970s. Originally limited to voice-only contact between patient and healthcare provider over the telephone, telehealth now makes use of an array of 21st century communications technology, including videoconferencing, the Internet, wireless, and satellite media. As of 2014, more than 200 telehealth networks are in the United States, and they link approximately 3,500 service sites, according to the American Telemedicine Association. In addition, more than 50% of all hospitals in the United States use some form of telemedicine, and about a million heart patients currently make use of remote cardiac monitors.

The federal government in the United States is also actively involved in the development of telehealth, particularly for remote or underserved populations, through such offices and programs as the Office for the Advancement of Telehealth (OAT), which is part of HRSA's Office of Rural Health Policy (ORHP), and the National Center for Telehealth and Technology, or "T2," which is part of the Department of Defense. Established in 2008, T2 provides mental health services (sometimes called "elemental health") via videoconferencing and mobile video calling to veterans diagnosed with **post-traumatic stress disorder** (PTSD) or traumatic brain injuries (TBIs).

Purpose

Telehealth has four main uses. One is direct access to primary care and referral to specialists. Primary care telehealth may involve either real-time videoconferencing or store-and-forward transmission of images, vital signs, and other patient data to a specialist. Videoconferencing technology allows for the use of digital stethoscopes, patient examination cameras, and other diagnostic equipment at the distant site.

Remote patient monitoring is an increasingly important use of telehealth, and is especially useful in the care of homebound patients, particularly those who live in remote areas or those with such chronic diseases as **congestive heart failure** (CHF), **asthma**, diabetes, depression, or **emphysema**. A central monitoring system is placed in the patient's home to record information from sensors or specialized blood pressure or blood glucose level monitors, and to transmit it to a remote diagnostic testing facility (RDTF) for interpretation and analysis. Remote patient monitoring can use either real-time or store-and-forward technology.

Personal access to medical and health information is important to many consumers. With the advent of electronic health records (EHRs) and online patient information portals provided by primary care physicians, many patients can log on from computers or mobile devices and obtain their personal health information and records. They can also request prescription refills from their physician, who in turn can transmit a script via e-mail to the patient's pharmacy.

Medical education, remote training, and consultation is the fourth major use of telehealth. Videoconferencing allows a consultant at a distant site to confer with a number of primary care providers at different originating sites, to demonstrate a procedure or technique, or to present a special education lecture or seminar to practitioners in remote locations.

WWW.BOOKBAZ.IR

Telehealth is important to consumers for a number of reasons. Perhaps the most important is its ongoing evolution as well as expansion. As new mobile, as well as stationary, telecommunications capabilities are developed, an increasingly larger number of consumers will be able to access more and more types of healthcare via telehealth, and to communicate with their providers as well as obtain online information about diseases, conditions, and treatments. Given the increasing speed of changes in this field, consumers should keep themselves informed about the latest communication devices and other developments in telehealth.

Improved access to healthcare is a major factor in consumer interest in telehealth. For many people, the thought of being able to have routine wellness check-ups or psychotherapy without having to drive to the doctor's office is appealing for the savings in time as well as gasoline. Other advantages may include:

- Improved patient compliance with therapy
- Fuller participation by patients who keep appointments via videoconferencing vs. those who may live in remote areas or are housebound and have difficulty getting to the doctor's office
- Better patient-kept records of their appointments (sometimes called "e-visits"), which they can then play back later if desired.
- Greater access to specialist care through referrals from the primary care physician, which can allow for faster diagnosis of potential problems before they become major health emergencies.

Telehealth has been shown to reduce healthcare costs in terms of travel time, more effective use of brick-and-mortar facilities, more efficient deployment of hospital staff and equipment, better monitoring of chronic diseases, fewer and shorter hospital stays, and fewer emergency room admissions. Telehealth has proven particularly useful in the treatment and **rehabilitation** of **stroke** patients and in intensive care unit (ICU) monitoring and care.

KEY TERMS

Distant site—The site where the telehealth physician or other healthcare provider is located. It is also known as the "hub site."

M-health—A term used for the practice of telehealth by mobile devices. It is also spelled mHealth.

Originating site—The site where the patient receiving telehealth care is located.

Real-time telehealth—Telehealth in which a telecommunications link (e.g., telephone, videoconferencing equipment, e-mail) allows for immediate communication. It is also called synchronous telehealth.

Store-and-forward telehealth—Telehealth in which images, video, or other patient data are captured and stored on a computer (or mobile device) and then transmitted (forwarded) at a later time to a specialist at another location for a diagnosis. Store-and-forward is also called asynchronous telehealth.

Telemedicine—The use of electronic communication and information technologies to provide or support clinical care at a distance. It may include case management and psychological counseling.

Telemental health—The practice of psychiatry or psychotherapy via videoconferencing or similar communications technology.

Telementoring—The use of audio, video, and other telecommunications and electronic information processing technologies to provide individual guidance or direction among healthcare professionals.

Telemonitoring—The use of communications technologies and electronic information processing to monitor the vital signs or general health status of a patient from a distance.

Risks

A number of studies have shown that the quality of healthcare in many fields delivered by telehealth is as good as that provided during face-to-face meetings between physician and patient. In some fields, particularly ICU care and psychiatry, telemedicine delivers better care, with improved outcomes and a higher degree of patient satisfaction.

On the other hand, telehealth is still a "work in progress" in many ways. One concern frequently expressed by consumers is privacy. The possibility that personal health information could be accessed, intercepted, or even altered by unauthorized persons is worrisome to many consumers. As of 2014, the Health Insurance Portability and Accountability Act (HIPAA) requires all telehealth networks in the United States to meet high security and privacy standards, including the use of data encryption during transmission and when the system is at rest.

Other consumers are concerned about the loss of a sense of presence between physician and patient. Even the best video equipment or voice transmission cannot fully substitute for face-to-face meetings or

consultations, and some consumers value this personal contact highly.

Connectivity is another important consumer concern as of 2014. The technological infrastructure needed to support telehealth equipment is not evenly distributed across the United States, and some consumers live in remote areas where access to affordable broadband is limited. Related to the issue of connectivity is reluctance on the part of some health care providers as well as patients to adopt the technology necessary to use telehealth. Some of this resistance to change is psychological, but some is also related to generational differences. Within the patient population, most adults have either grown up with computers and mobile devices or learned to use them in the 1970s and 1980s, and feel comfortable with them. A sizable number of elderly persons, however, are not accustomed to using e-mail and similar electronic means of communication, or view home health monitoring equipment as obtrusive or an invasion of their privacy.

The remaining major concern about telehealth is the complex and uneven schedules of reimbursement for telehealth services. Medicare, as well as private insurance companies, have varying policies—some of which are very confusing to consumers—when it comes to covering the cost of telehealth services. Some states require insurance companies to cover telehealth services at the same rate as face-to-face visits. Some insurers cover at least some telehealth services, and still others are considering expanding their coverage of telehealth. Consumers with private health insurance should check with their benefits manager to find out whether their policy covers telehealth, and if so, what specific services are covered.

Temporal arteritis

Definition

The term temporal arteritis literally means "inflammation of the temporal arteries." As implied by the name, these blood vessels run along the temples after they branch off from the carotid artery in the neck. They provide the blood supply to portions of the scalp, jaw muscles, and salivary glands. Inflammation of these arteries, probably resulting from an abnormal immune reaction, disrupts this blood supply, resulting in a variety of symptoms. They can range from relatively minor jaw **pain** or **headache** to major symptoms, including temporary or permanent blindness.

Temporal arteritis is also called giant cell arteritis or cranial arteritis. It is a rheumatic disease that affects large–and medium–sized arteries throughout the body and can occur in a variety of patients. Although the temporal arteries are most commonly affected, other arteries throughout the body may be affected. The disease seems to target arteries containing elastic tissue. Veins are rarely affected. Temporal arteritis is a type of **vasculitis**.

Demographics

Temporal arteritis almost always occurs in people over 50, and it becomes more common as people age. About 20 out of 100,000 people over the age of 50 have temporal arteritis. Women are affected twice as often as men. Some authorities say that temporal arteritis is more common in Caucasians (especially Scandinavians) than in people of other races. Close relatives of patients with temporal arteritis may be more likely than others to get the disease.

Description

Patients with temporal arteritis are diagnosed and overlap with a broader disorder called giant cell arteritis. This disorder can affect parts of the body in addition to the scalp, eyes, and jaw. Sometimes the disease can cause restricted circulation to both arms or both legs, producing pain in the affected limbs. With other blood vessels involved, patients with advanced forms of the disease may experience strokes or transient ischemic attacks (TIA). These result in brief episodes of pain caused by decreased blood flow. Even heart attacks are occasionally caused by giant cell arteritis.

Causes and symptoms

This disease is one of a group of diseases in which the linings of large–or medium–sized blood vessels become inflamed. The elastic layer of these vessels is attacked by "giant" cells and chemicals produced by the immune system. This reaction reduces blood flow through the blood vessels, and the limited blood supply causes the symptoms.

The disease usually begins with "flu–like" symptoms, including a mild **fever** (100–101°F; 37.8–38.3°C), general body discomfort, and a persistent, dull headache. The scalp may be tender to the touch over the affected blood vessels. Jaw muscles sometimes become painful when the patient chews.

As the disease progresses, more severe symptoms occur. These include blurred vision or temporary blindness that typically lasts ten minutes or less. Eventually, permanent loss of vision can occur. Transient ischemic attacks, strokes, and heart attacks may occur when the disease is far advanced.

Diagnosis

Doctors from a number of specialties develop experience in diagnosing and treating temporal arteritis. These include internists, who treat a broad range of diseases; rheumatologists, who focus on rheumatic diseases; geriatricians, who treat older people; ophthalmologists, who treat eye and vision disorders; neurologists, who treat headaches and problems of the optic nerve; and vascular surgeons, who treat blood vessel problems.

The doctor will generally take a medical history first. The patient can help the doctor tremendously by reviewing all symptoms—both major and minor—from the last two or three months. If possible, the patient should ask family or close friends for help in recalling his or her ailments from recent months. Then the doctor will conduct a complete

Biopsy—Removal and examination of a sample tissue from the body for diagnostic purposes.

Corticosteroids—A group of hormones, produced naturally by the adrenal gland and other organs. They are used to treat a wide variety of disorders, including many rheumatic disorders.

Erythrocyte sedimentation rate—The speed at which red blood cells sink in a tube of freshly drawn blood, which is a rough measure of clotting disorders or inflammation.

Prednisone—A corticosteroid often used to treat inflammation.

Rheumatic disease—A type of disease involving inflammation of muscles, joints, and other tissues.

Vasculitis—An inflammation of the blood vessels.

physical examination. Often, he or she will detect a tender, swollen artery on the scalp.

The doctor will order blood tests as well. A standard and inexpensive test called the **erythrocyte sedimentation rate** (ESR or "sed" rate) is particularly helpful. Results from this test, which measures inflammation in the body, will almost always be higher than normal. Tests of red blood cells may show mild anemia. Sometimes blood tests for liver function will also be abnormal.

The definitive diagnostic test is a temporal artery biopsy. A doctor will make one or more tiny incisions under local **anesthesia** to remove samples of the suspect artery. Under the microscope, a pathologist usually can identify the typical damage caused by temporal arteritis.

Treatment

The mainstay of treatment is a course of **corticosteroids** (steroid hormones that have an anti–inflammatory effect), usually prednisone. The initial prescription involves a fairly high dose of **steroids** (40–60 mg/day) that is gradually tapered down to a maintenance dose. Because of the high incidence of blindness in untreated cases, steroid therapy should be started immediately rather than waiting for biopsy results. Patients typically take this maintenance dose for periods of one to three years. Sometimes nonsteroidal anti–inflammatory drugs (NSAIDs) are prescribed for muscle aches or headaches, especially while steroid doses are being reduced.

Prognosis

The outlook for most patients with temporal arteritis is good, especially if the disorder is diagnosed early. Symptoms often diminish within a month once patients begin to take steroids. Although physicians do not talk about a "cure" for temporal arteritis, symptoms typically do not return after a full course of steroid treatment. If the diagnosis is made late in the disease, lost vision may not return.

Prevention

There is no medically proven approach to prevention. The best way to prevent severe, permanent damage is to obtain expert medical advice if the patient or the family physician suspects this problem.

Temporomandibular joint disorders

Definition

Temporomandibular joint disorder (TMJ) is the name given to a group of symptoms that cause **pain** in the head, face, and jaw. The symptoms include headaches, soreness in the chewing muscles, and clicking or stiffness of the joints. They often have psychological as well as physical causes.

Demographics

The disorder has been observed in both male and female populations, and across all age groups. Several precipitating factors such as injury, jaw alignment, jaw structure, and ligament connectivity may predispose an individual to TMJ disorder.

Description

TMJ disorder, which is also sometimes called TMJ syndrome, results from pressure on the facial nerves due to muscle tension or abnormalities of the bones in the area of the hinge joint between the lower jaw and the temporal bone. This hinge joint is called the temporomandibular joint. There are two temporomandibular joints, one on each side of the skull just in front of the ear. The name of the joint comes from the two bones that make it up. The temporal bone is the name of the section of the skull bones where the jaw bone (the mandible) is connected. The jaw bone is held in place by a combination of ligaments, tendons, and muscles. The temporomandibular joint also contains a piece of cartilage called a disc, which keeps the temporal bone and the jaw bone from rubbing against each other. The jaw pivots at the joint area in front of the ear. The pivoting motion of the jaw is complicated because it can move downward and from side to side as well as forward. Anything that causes a change in shape or functioning of the temporomandibular joint will cause pain and other symptoms.

Causes and symptoms

Causes

TMJ syndrome has several possible physical causes:

- Muscle tension. Muscle tightness in the temporomandibular joint usually results from overuse of muscles. This overuse in turn is often associated with psychological stress and clenching or grinding of the teeth (bruxism).
- Injury. A direct blow to the jaw or the side of the head can result in bone fracture, soft tissue bruising, or a dislocation of the temporomandibular joint itself.
- Arthritis. Both osteoarthritis and rheumatoid arthritis can cause TMJ.
- Internal derangement. Internal derangement is a condition in which the cartilage disk lies in front of its proper position. In most cases of internal derangement,

the disc moves in and out of its correct location, making a clicking or popping noise as it moves. In a few cases, the disc is permanently out of position, and the patient's range of motion in the jaw is limited.

- Hypermobility. Hypermobility is a condition in which the ligaments that hold the jaw in place are too loose and the jaw tends to slip out of its socket.
- Birth abnormalities. These are the least frequent cause of TMJ but do occur in a minority of patients. In some cases, the top of the jawbone is too small; in others, the top of the jawbone outgrows the lower part.

Symptoms

The symptoms of TMJ depend in part on its cause. The most common symptoms are facial pain in front of the ears; headaches; sore jaw muscles; a clicking sound when chewing; a grating sensation when opening and closing the mouth; and temporary locking of the jaw. Some patients also report a sensation of buzzing or ringing in the ears. Usually, the temporomandibular joint itself is not painful. Most cases of TMJ are seen in women 20–50 years of age.

Diagnosis

Dental examination and patient history

TMJ disorders are most frequently diagnosed by dentists. The dentist can often diagnose TMJ based on **physical examination** of the patient's face and jaw. The examination might include pressing on (palpating) the jaw muscles for soreness or asking the patient to open and close the jaw in order to check for misalignment of the teeth in the upper and lower jaw. This condition is called **malocclusion**. The dentist might also gently move the patient's jaw in order to check for loose ligaments.

Imaging studies

Imaging studies are not usually necessary to diagnose TMJ. In most cases, x rays and MRI scans of the temporomandibular joint will be normal. Consequently, these two tests are not commonly used to diagnose TMJ. If the dentist suspects that the patient has internal derangement of the disc, he or she can use a technique called **arthrography** to make the diagnosis. In an arthrogram, a special dye is injected into the joint, which is then x rayed. Arthrography can be used to evaluate the movement of the jaw and the disc as well as size and shape, and to evaluate the effectiveness of treatment for TMJ.

Treatment

In many cases, the cause of pain in the TMJ area is temporary and disappears without treatment. About 80% of patients with TMJ will improve in six months without medications or physical treatments.

KEY TERMS

Arthrography—An imaging technique that is sometimes used to evaluate TMJ associated with internal derangement.

Bruxism—Habitual clenching and grinding of the teeth, especially during sleep.

Electromyographic biofeedback—A method for relieving jaw tightness by monitoring the patient's attempts to relax the muscle while the patient watches a gauge. The patient gradually learns to control the degree of muscle relaxation.

Internal derangement—A condition in which the cartilage disc in the temporomandibular joint lies in front of its proper position.

Malocclusion—The misalignment of opposing teeth in the upper and lower jaws.

Mandible—The medical name for the lower jaw.

Osteoarthritis—A type of arthritis marked by chronic degeneration of the cartilage of the joints, leading to pain and sometimes loss of function.

Rheumatoid arthritis—A chronic autoimmune disorder marked by inflammation and deformity of the affected joints.

Temporal bones—The compound bones that form the left and right sides of the skull.

Transcutaneous electrical nerve stimulation—A method for relieving the muscle pain of TMJ by stimulating nerve endings that do not transmit pain. Authorities believe that this stimulation blocks impulses from nerve endings that do transmit pain.

Medications

Patients with TMJ can be given **muscle relaxants** if their symptoms are related to muscle tension. Some patients may be given **aspirin** or nonsteroidal anti–inflammatory drugs (NSAIDs) for minor discomfort. If the TMJ is related to **rheumatoid arthritis**, it may be treated with **corticosteroids**, methotrexate (MTX, Rheumatrex) or gold **sodium** (Myochrysine).

Physical therapy and mechanical devices

Patients who have difficulty with **bruxism** are usually treated with splints. A plastic splint called a nightguard is given to the patient to place over the

WWW.BOOKBAZ.IR

teeth before going to bed. Splints can also be used to treat some cases of internal derangement by holding the jaw forward and keeping the disc in place until the ligaments tighten. The splint is adjusted over a period of two to four months.

TMJ can also be treated with **ultrasound**, electromyographic **biofeedback**, stretching exercises, transcutaneous **electrical nerve stimulation**, **stress** management techniques, or friction massage.

Surgery

Surgery is ordinarily used only to treat TMJ caused by birth deformities or certain forms of internal derangement caused by misshapen discs.

Prognosis

The prognosis for recovery from TMJ is excellent for almost all patients. Most patients do not need any form of long–term treatment. Surgical procedures to treat TMJ are quite successful. In the case of patients with TMJ caused by arthritis or infectious diseases, the progression of the arthritis or the success of eliminating infectious agents determines whether TMJ can be eliminated.

Tendinitis

Definition

Tendinitis is the inflammation of a tendon, a tough rope-like tissue that connects muscle to bone.

Description

Tendinitis usually occurs in individuals in middle or old age because it is often the result of overuse over a long period of time. Tendinitis does occur in younger patients as a result of acute overuse.

Tendons that commonly become inflamed include:

- tendons of the hand
- tendons of the upper arm that effect the shoulder
- Achilles' tendon and the tendon that runs across the top of the foot

Causes and symptoms

Sudden stretching or repeated overuse injures the connection between the tendon and its bone or muscle. The injury is largely mechanical, but when it appears, the body tries to heal it by initiating inflammation. Inflammation increases the blood supply, bringing nutrients to the damaged tissues along with immunogenic agents to combat infection. The result is swelling, tenderness, **pain**, heat, and redness if the inflammation is close to the skin.

Diagnosis

Some tendon injuries are superficial and easy to identify. These include "tennis elbow" (extensor tendinitis) over the outside of the elbow, and Achilles' tendinitis just above the heel of the foot. There are several tendons in the shoulder that can be overused or stretched, and usually a shoulder will have more than one injury at a time. Tendinitis in the biceps, the infraspinatus, or the supraspinatus tendon may accompany a tear of the shoulder ligaments or an impingement of one bone or another. Careful pressure testing and movement of the parts is all that is necessary to identify the tendinitis.

Treatment

Rest, ice, compression, and elevation (RICE) will treat the acute condition. The best way to apply ice is in a bag with water. The water applies the cold directly to the skin. Chemical ice packs can get too cold and cause frostbite. Compression using an elastic wrap minimizes swelling and bleeding in an acute sprain. Splinting may help rest the limb. Pain and anti-inflammatory medications (**aspirin**, naproxen, ibuprofen) will help. Sometimes the inflammation lingers and requires additional treatment. Injections of cortisone-like medicine often relieve chronic tendinitis, but should be reserved for resistant cases since cortisone can occasionally cause problems of its own.

If tendinitis is persistent and unresponsive to nonsurgical treatment, a surgery to remove the afflicted portion of tendon can be performed. Surgery is also

Infraspinatus—A muscle at the middle of the shoulder blade.

Supraspinatus—A muscle at the top of the shoulder blade.

conducted to remove **calcium** buildup that comes with persistent tendinitis.

Alternatives

An osteopathic soft-tissue treatment on the tendon may relieve pain and increase mobility. Increasing intake of antioxidant-rich foods and lowering intake of animal fats may help reduce the inflammation. **Acupuncture** has also been used to combat tendinitis. Hydrotherapies, such as whirlpool baths, help relax the surrounding muscles.

Prognosis

Generally, tendinitis will heal if the provoking activity is stopped.

Prevention

If given enough time, tendons will strengthen to meet the demands placed on them. They grow slowly because of their poor blood supply, so adequate time is required for good conditioning.

Tennis elbow

Definition

Tennis elbow is an inflammation of several structures of the elbow. These include muscles, tendons, bursa, periosteum, and epicondyle (bony projections on the outside and inside of the elbow, where muscles of the forearm attach to the bone of the upper arm).

Demographics

Tennis elbow is most common in adults ages 30 to 50, but the condition can affect anyone who repetitively stresses the wrists. Anyone who uses repetitive movements for at least two hours a day is at greater risk. People who smoke also have a higher risk of developing tennis elbow.

Description

The classic tennis elbow is caused by repeated forceful contractions of wrist muscles located on the outer forearm. The **stress**, created at a common muscle origin, causes microscopic tears leading to inflammation. This is a relatively small surface area located at the outer portion of the elbow (the lateral epicondyle). Medial tennis elbow, or medial epicondylitis, is caused by forceful, repetitive contractions from muscles located on the inside of the forearm. All of the forearm muscles are involved in tennis serves, when combined motions of the elbow and wrist are employed. This overuse injury is common between ages 20 and 40.

People at risk for tennis elbow are those in occupations that require strenuous or repetitive forearm movement. Such jobs include mechanics or carpentry. Sport activities that require individuals to twist the hand, wrist, and forearm, such as tennis, throwing a ball, bowling, golfing, and skiing, can cause tennis elbow. Individuals in poor physical condition who are exposed to repetitive wrist and forearm movements for long periods of time may be prone to tennis elbow. This condition is also called epicondylitis, lateral epicondylitis, medial epicondylitis, or golfer's elbow, where **pain** is present at the inside epicondyle.

Causes and symptoms

Tennis elbow pain originates from a partial tear of the tendon and the attached covering of the bone. It is caused by chronic stress on tissues attaching forearm muscles known as extensor muscles to the elbow area. Individuals experiencing tennis elbow may complain of pain and tenderness over either of the two epicondyles. This pain increases with gripping or rotation of the wrist and forearm. If the condition becomes long-standing and chronic, a decrease in grip strength can develop.

Diagnosis

Diagnosis of tennis elbow includes the individual observation and recall of symptoms, a thorough medical history, and **physical examination** by a physician. Diagnostic testing is usually not necessary unless there

may be evidence of nerve involvement from underlying causes. X rays are usually always negative because the condition is primarily soft tissue in nature, in contrast to a disorder of the bones. However, **magnetic resonance imaging** (MRI) has been shown to be helpful in diagnosing cases of early tennis elbow because it can detect evidence of swelling and tissue tears in the common extensor muscle group.

Treatment

Conservative

Heat or ice is helpful in relieving tennis elbow pain. Once acute symptoms have subsided, **heat treatments** are used to increase blood circulation and promote healing. The physician may recommend **physical therapy** to apply diathermy or **ultrasound** to the inflamed site. These are two common modalities used to increase the temperature of the tissues in order to address both pain and inflammation. Occasionally, a tennis elbow splint or taping may be useful to help decrease stress on the elbow throughout daily activities. Exercises become very important to improve flexibility to all forearm muscles, and will aid in decreasing muscle and tendon tightness that has been creating excessive pull at the common attachment of the epicondyle.

The physician may also prescribe **nonsteroidal anti-inflammatory drugs** (NSAIDS) to reduce inflammation and pain. Injections of cortisone or anesthetics are often used if physical therapy is ineffective. Cortisone reduces inflammation, and anesthetics temporarily relieve pain. Physicians are cautious regarding an excessive number of injections as they have been found to weaken the tendon's integrity. In addition, a significant number of patients experience a temporary increase in pain following corticosteroid injections.

KEY TERMS

Epicondyle—A projection on the surface of a bone; often an area for muscle and tendon attachment.

Epicondylitis—A painful and sometimes disabling inflammation of the muscle and surrounding tissues of the elbow caused by repeated stress and strain on the forearm near the lateral epicondyle of the humerus (arm bone).

Extensor muscles—A group of muscles in the forearm that serve to lift or extend the wrist and hand. Tennis elbow results from overuse and inflammation of the tendons that attach these muscles to the outside of the elbow.

Periosteum—A fibrous vascular membrane that covers bones.

Shock wave therapy—A method of treating tennis elbow and other musculoskeletal injuries that involves directing bursts of high-pressure sound waves at the affected area.

A newer method of treatment for tennis elbow is shock wave therapy, in which pulses of high-pressure sound are directed at the injured part of the tendon. The "shock" refers to the high pressure, which breaks down scar tissue and stimulates the regrowth of blood vessels in healthy tissue. Shock wave therapy sessions take about 20 minutes and the treatment has very few side effects; one group of German physicians found that temporary reddening of the skin or small **bruises** were the most commonly reported side effects. Initially reported to have a succes rate of 80%, newer studies have shown shock wave therapy to be less effective than previously thought.

Botulinum toxin, or Botox, is also being tried as a treatment for tennis elbow. Although further research needs to be done, Botox appears to relieve pain in chronic tennis elbow by relaxing muscles that have gone into spasm from prolonged inflammation.

Surgery

If conservative methods of treatment fail, surgical release of the tendon at the epicondyle may be a necessary form of treatment. However, surgical intervention is relatively rare.

Alternatives

Massage therapy has been found to be beneficial if symptoms are mild. Massage techniques are based primarily on increasing circulation to promote efficient reduction of inflammation. Manipulation, **acupuncture**, and **acupressure** have been used as well. Contrast **hydrotherapy** (alternating hot and cold water or compresses, three minutes hot, 30 seconds cold, repeated three times, always ending with cold) applied to the elbow can help bring nutrient-rich blood to the joint and carry away waste products. Botanical medicine and homeopathy may also be effective therapies for tennis elbow. For example, cayenne (*Capsicum frutescens*) ointment or prickly ash (*Zanthoxylum americanum*) oil applied topically may help to increase blood flow to the affected area and speed healing.

Prognosis

Tennis elbow is usually curable; however, if symptoms become chronic, it is not uncommon for treatment to continue for three to six months.

Prevention

Until symptoms of pain and inflammation subside, activities requiring repetitive wrist and forearm motion should be avoided. Once pain decreases to the point that return to activity can begin, the playing of sports, such as tennis, for long periods should not occur until excellent condition returns. Many times, choosing a different size or type of tennis racquet may help. Frequent rest periods are important despite what the wrist and forearm activity may be. Compliance with a stretching and strengthening program is very important in helping prevent recurring symptoms and exacerbation.

TENS *see* **Electrical nerve stimulation**

Tensilon test

Definition

Tensilon is the trade name for edrophonium chloride. The Tensilon test is an injection of edrophonium chloride used to diagnosis **myasthenia gravis** (MG).

Purpose

Tensilon blocks the action of an enzyme, acetylcholinesterase, an important part of the system regulating neuromuscular transmission. To stimulate a muscle, a nerve cell (neuron) releases the chemical acetylcholine. To prevent prolonged muscle response to a single nerve signal, acetylcholine is broken down by acetylcholinesterase after the muscle is stimulated.

In myasthenia gravis, there are too few receptors for acetylcholine on the muscle. The acetylcholine is broken down before it can fully stimulate this reduced number of receptors, and, as a result, the muscle is weak. By blocking the action of acetylcholinesterase, Tensilon prolongs the muscle stimulation, and temporarily improves strength. Increased strength following an injection of Tensilon strongly suggests a dignosis of MG. The Tensilon test is most effective when easily observed weakness is present, and is less useful for vague or fluctuating complaints.

Precautions

The Tensilon test may cause heart rhythm abnormalities, especially in those patients with preexisting conditions.

Description

The Tensilon test involves the intravenous injection of a small amount of Tensilon. The needle is left in place. If no adverse reaction is observed within 30 seconds, an additional volume is injected. Results are apparent within one minute.

KEY TERMS

Acetylcholine—A molecule released by neurons at the neuromuscular junction that causes muscle contraction.

Preparation

Before the test, the patient must stop taking all drugs that can inhibit acetylcholinesterase. The referring physician can advise on specific drugs the patient is taking.

Aftercare

The effects of Tensilon subside quickly, and are completely gone after 30-60 minutes. No aftercare is needed.

Risks

Atrial fibrillation and bradycardia are possible in sensitive individuals. The administering physician must have appropriate resuscitative equipment available.

Results

In a patient without MG, the Tensilon test will not produce an obvious increase in a previously weak muscle. Some subjective feelings of increased strength are possible but not significant.

Abnormal results

An obvious increase in strength in weakened muscles strongly suggests the diagnosis of myasthenia gravis. The effect comes on very rapidly, and fades within minutes.

Tension headache

Definition

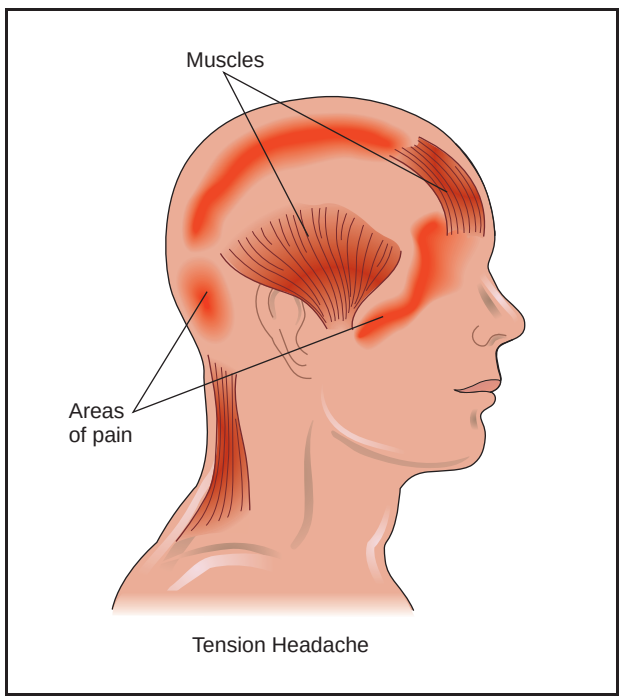
This most common type of **headache** is caused by severe muscle contractions triggered by **stress** or exertion. Tension headaches are considered a type of primary headache, which means that they are not caused by another medical condition or disorder.

Other names for tension headaches include muscle contraction headache, ordinary headache, psychomyogenic headache, and stress headache.

Demographics

The American Council for Headache Education (ACHE) estimates that 95% of women and 90% of men in the United States and Canada have had at least one headache in the past twelve months.

In terms of age groups, chronic tension headaches have been reported in children younger than six years, but most people report that their tension headaches start in adolescence or the early twenties.



Tension headache is the most common type of headache caused by severe muscle contractions triggered by stress or exertion. Tension headaches usually occur in the front of the head, although they may also appear at the top or the back of the skull, as shown. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

While most American adults get a tension headache from time to time, women and people with more education are slightly more likely to experience them; the female: male ratio is reported to be 1.4: 1. People who are so anxious that they grind their teeth or hunch their shoulders may find that the physical strain in their body can be experienced as **pain** and tension in the muscles of the neck and scalp, producing almost constant pain.

Causes and symptoms

Tension headaches are caused by tightening in the muscles of the face, neck and scalp because of stress or poor posture. They can last for days or weeks and can cause pain of varying intensity. The tightening muscles cause more expansion and constriction of blood vessels, which can make head pain worse. Eyestrain caused by dealing with a large amount of paperwork or reading can cause a tension headache as well.

Many people report tension headache pain as a kind of steady ache (as opposed to a throb) that forms a tight band around the forehead, affecting both sides of the head. Tension headaches usually occur in the front of the head, although they also may appear at the top or the back of the skull.

Tension headaches often begin in late afternoon and can last for several hours. They can occur every day and last throughout most of the day, but most (82%) go away within a few hours. A tension headache that occurs 15 or more days per month over a period of six months or longer is called a chronic tension headache. Unlike migraines, tension headaches do not cause **nausea and vomiting**, sensitivity to light, or any kind of aura before the headache begins.

It is possible for children as well as adults to have more than one type of headache. It is not unusual for patients with chronic tension headaches to have migraine headaches as well.

Diagnosis

Diagnosis of tension headaches is made from a medical history, discussion of symptoms, and elimination of other types of headaches or underlying disorders.

Very few headaches are the sign of a serious underlying medical problem. However, an individual should call a physician at once if they:

- have more than three headaches a week
- take painkillers almost every day
- need more than the recommended dose of painkiller
- have a stiff neck and/or fever in addition to headache

WWW.BOOKBAZ.IR

KEY TERMS

Analgesic—A medication that relieves pain without causing loss of consciousness. Over–the–counter analgesics include aspirin and NSAIDs.

Primary headache—A headache that is not caused by another disease or medical condition. Tension headaches are a subtype of primary headache.

Rebound headache—A type of primary headache caused by overuse of pain relievers. It is also known as analgesic abuse headache.

- are dizzy, unsteady, or have slurred speech, weakness, or numbness
- have confusion or drowsiness with the headache
- have headaches that began with a head injury
- have headaches triggered by bending, coughing or exertion
- have headaches that keep getting worse
- have severe vomiting with the headache
- have the first headache after age 50
- awaken with headache that gets better as the day goes on

Treatment

There are many different treatments for tension headaches, which respond well to both medication and massage. If these headaches become chronic, however, they are best treated by identifying the source of tension and stress and reducing or eliminating it.

Medication

Tension headaches usually respond very well to such over–the–counter **analgesics** as **aspirin**, ibuprofen, or **acetaminophen**. Some of these drugs (especially those that contain **caffeine**) may trigger rebound headaches if discontinued after they are taken for more than a few days.

More severe tension headaches may require combination medications, including a mild sedative such as butalbital; these products should be used sparingly. Chronic tension headaches may respond to low–dose amitriptyline taken at night.

Massage

Massaging the tense muscle groups may help ease pain. Instead of directly massaging the temple, patients will get more relief from rubbing the neck and shoulders, because tension headaches can arise from tension in this area. In fact, relaxing the muscles of the neck can cut the intensity and duration of tension headaches at least in half.

To relax these muscles, the neck should be rotated from side to side as the shoulders shrug. Some people find that imagining a sense of warmth or heaviness in the neck muscles can help. Taking three very deep breaths at the first hint of tension can help prevent a headache.

Other therapy

If tension headaches are a symptom of either depression or **anxiety**, the underlying problem should be treated with counseling, medication, or a combination of both.

Injections of botulinum toxin (Botox) have been reported to relieve tension headaches in some patients.

Alternatives

Eliminating the source of the tension as much as possible will help prevent tension headaches. **Acupuncture** may be helpful in treating some chronic tension headaches. Homeopathic remedies and botanical medicine can also help relieve tension headaches. Valerian (*Valeriana officinalis*), skullcap (*Scutellaria lateriflora*), and passionflower (*Passiflora incarnata*) are three herbal remedies that may be helpful. A tension headache can also be relieved by soaking the feet in hot water while an ice cold towel is wrapped around the neck.

Prognosis

Cutting down on stress and relying less on caffeine–containing medications can reduce the number of tension headaches for most people.

Prevention

Tension headaches can often be prevented by managing everyday stress and making some important lifestyle changes. Those who are prone to tension headaches should:

- take frequent "stress breaks"
- get regular exercise—even a brisk 15–minute walk can help prevent tension headaches
- get enough sleep
- release angry feelings

Testicular cancer

Definition

Testicular cancer is a disease in which cancer cells are discovered in one or both testicles. The testicles, also known as testes or gonads, are located in a pouch beneath the penis called the scrotum.

Demographics

The American Cancer Society estimated that approximately 8,400 new cases of testicular cancer were diagnosed in American men in 2009. In addition, an estimated 380 men died of the disease in 2009. There is a 1 in 300 probability of developing testicular cancer. The disease is highly curable and the risk of dying from testicular cancer is very low. Only 1 in every 5,000 men diagnosed with testicular cancer die from their cancer. Although the incidence of testicular cancer is rising, having doubled since the 1970s, it is still rare. Scandinavian countries have the highest rate in the world. Germany and New Zealand also have high rates. The lowest incidences of testicular cancer are in Asia and Africa.

A cancerous growth on the testicle. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

The testicles make up one portion of the male reproductive system. Normally, they are each somewhat smaller than a golf ball in size and are contained within the scrotum. The testicles are a man's primary source of male hormones, particularly testosterone. They also produce sperm.

There are several types of cells contained in the testicles, and any of these may develop into one or more types of cancer. More than 95% of all testicular cancers begin in cells called germ cells. There are two main types of **germ cell tumors** in men: seminomas and nonseminomas. Seminomas make up about 40% of all testicular germ cell tumors. Nonseminomas make up a group of cancers, which include **choriocarcinoma**, yolk sac tumors, embryonal carcinoma, and teratoma. Clinically, nonseminomatous tumors are the more aggressive tumor type.

Although testicular cancer accounts for less than 2% of all cancers in men, it is the most commonly seen cancer in young men aged 15 to 35. It is also one of the most curable.

Risk factors

There is research showing that some men are more likely to develop testicular cancer than others. The risk for testicular cancer is much higher for boys born with one or both of their testicles located in the lower abdomen rather than in the scrotum. This condition is called cryptorchidism or undescended testicles. The lifetime risk of being diagnosed with testicular cancer is four times higher for boys with cryptorchidism than the risk in the general population. This risk factor remains even if surgery is done to place the testicle back into the scrotum.

Boys born with **Down syndrome** are also at higher risk of developing testicular cancer, although the reasons for this increased risk are not yet fully understood.

There are other risk factors as well. Men who have had abnormal development of their testicles are at increased risk, as are men with Klinefelter's syndrome (a disorder of the sex chromosomes). A family history of testicular cancer increases the possibility of getting the disease. Men infected with the human **immunodeficiency** virus (HIV), especially those with **AIDS**, have a higher incidence, as do infertile men. Certain testicular tumors appear more frequently among men who work in certain occupations, like miners, oil workers, and utility workers. There is no conclusive evidence that injuries to the testicles, or environmental exposure to various chemicals causes the disease.

Causes and symptoms

The exact causes of testicular cancer are unknown; although, a number of risk factors have been identified which, when present, seem to place some men at higher risk for the development of this type of cancer.

Testicular cancer usually shows no early symptoms with only 25% of men experiencing symptoms. It is suspected when a mass or lump is felt in the testes, although a testicular mass does not always indicate cancer and is usually painless.

Symptoms of testicular cancer include:

- a lump in either testicle (usually pea-sized, but may be as large as a marble or an egg)
- any enlargement or significant shrinking of a testicle
- a sensation of heaviness in the scrotum
- a dull ache in the groin or lower abdomen
- any sudden collection of fluid in the scrotum
- tenderness or enlargement of the breasts
- pain or discomfort in a testicle or in the scrotum

Other symptoms, such as **pain** in the lower back, **shortness of breath**, chest pain, **cough**, abdominal

pain, and headaches, may be present if the cancer is advanced and has spread to the lymph nodes in the abdomen, the lungs and/or the brain.

Diagnosis

When a man exhibits symptoms that suggest a possibility of testicular cancer, several diagnostic steps will occur before a definitive diagnosis is made.

Examination

The physician conducts a personal and family medical history and a complete **physical examination** is performed. The doctor will examine the scrotum as well as the abdomen and other areas to check for additional masses.

Tests

If a mass is found, an **ultrasound** of the testicles is performed. Through the use of sound waves, ultrasounds can help visualize internal organs and may be useful in telling the difference between fluid-filled cysts and solid masses.

Computed tomography (CT scan) as well as ultrasound may be used to diagnose malignant germ cell tumors in **undescended testes**. CT scans are also used to determine if the cancer has spread to other areas of the body outside of the testes.

A chest x ray may be done to see if the cancer has spread to the lungs and/or to the lymph nodes in the thoracic area. Other imaging tests which may be ordered include a **magnetic resonance imaging** (MRI) scan and/or a **positron emission tomography** (PET) scan.

Certain blood tests can be helpful in diagnosing some testicular tumors. **Tumor markers** are substances often found in higher-than-normal amounts in cancer patients. Some testicular cancers secrete high levels of certain proteins such as alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG), and enzymes like lactate dehydrogenase (LDH). These markers may help find a tumor that is too small to be felt during a physical examination. In addition, these tests are helpful in determining how much cancer is actually present, and in evaluating the response to treatment to make sure the tumor has not returned.

AFP is a tumor marker produced by nonseminomatous testicular tumors. Elevated HCG levels may be secreted by seminomas and nonseminoma tumors. Pure seminomas are not associated with elevated AFP levels. Some testicular tumors contain elements of both seminoma and nonseminoma tumors. In that case, the tumor is clinically managed as a nonseminoma.

Procedures

If a suspicious growth is found, a surgeon will need to remove the tumor and send it to the laboratory for testing. A pathologist examines the testicular tissue microscopically to determine whether cancer cells are present. If cancer cells are found, the pathologist sends back a report describing the type and extent of the cancer. In almost all cases, the surgeon removes the entire affected testicle through an incision in the groin, though not through the scrotum. This procedure is called radical inguinal orchiectomy.

Once testicular cancer is determined, further tests are necessary to find out if the cancer has metastasized (spread) to other parts of the body, and to ascertain the stage or extent of the disease. This information helps the doctor plan appropriate treatment. These tests may include abdominopelvic computed tomography (CT scan), bone scans, and chest x rays.

Treatment

Staging

One method the cancer treatment team uses to describe the scope of a patient's cancer is the use of a staging system. Testicular cancer is classified using the TNM system. In order to simplify and summarize this information, the TNM description can be grouped according to stages.

Stages of testicular cancer:

- Stage I. This stage refers to a cancer found only in the testicle, with no spread to the lymph nodes or to distant organs.
- Stage II. This indicates that the cancer has spread to the lymph nodes in the abdomen, but not to lymph nodes in other parts of the body.
- Stage III. In this stage, the cancer has spread beyond the lymph nodes in the abdomen, and/or the cancer is in parts of the body far away from the testicles, such as the lungs or the liver.
- Recurrent. Recurrent disease indicates that the cancer has come back after it has already been treated. Testicular cancer can come back in the same testicle (if it was not surgically removed) or in some other body part.

Treatment

The treatment decisions for testicular cancer are dependent on the stage and cell type of the disease, as well as the patient's age and overall health. The four kinds of treatment most commonly used are surgery, **radiation therapy**, **chemotherapy**, and bone marrow or **stem cell transplantation**.

WWW.BOOKBAZ.IR

Patients diagnosed with testicular cancer should be provided with information regarding fertility preservation options, including sperm banking, prior to the start of treatment.

Surgery is normally the first line of treatment for testicular cancer and involves the removal of the affected testicle. This procedure is known as a radical inguinal orchiectomy. Depending on the type and stage of the cancer, some lymph nodes may also be removed at the same time, or possibly in a second operation. This procedure is called a retroperitoneal lymph node dissection, and can be a major operation. Some patients will experience temporary complications after surgery, including infections and bowel obstruction. If both of the testicles are taken out, a man will have no ability to produce sperm cells and will become infertile (unable to father a child). Surgery removing the lymph nodes may cause some damage to nearby nerves, which may interfere with the ability to ejaculate. Men undergoing surgery for testicular cancer may wish to discuss nerve-sparing surgery with their doctor, as well as sperm banking.

Radiation therapy for testicular cancer is delivered from a machine and is known as external beam radiation. One potential problem with this type of radiation is that it can also destroy nearby healthy tissue as well as cancer cells. Other potential side effects include nausea, **diarrhea** and **fatigue**. A special device can be used to protect the unaffected testicle to preserve fertility. Seminomas are very sensitive to the effects of radiation therapy.

Chemotherapy refers to the use of drugs in treating cancer. Since the drugs enter the bloodstream and circulate throughout the body, chemotherapy is considered a systemic treatment. The drugs primarily used in the treatment of testicular cancer are cisplatin, vinblastine, bleomycin, carboplatin, cyclophosphamide, etoposide, ifosfamide, paclitaxel, mesna, gemcitabine, and oxaliplatin. These drugs are given in various combinations, since the use of two or more drugs is considered more effective than using only one drug.

Since chemotherapy agents can affect normal as well as cancerous cells, several side effects are possible. These side effects include:

- nausea and vomiting
- changes in appetite (anorexia)
- temporary hair loss (alopecia)
- mouth sores
- increased risk of infections
- bleeding or bruising
- fatigue
- diarrhea or constipation

Several drugs are available to assist in treating these side effects, most of which will disappear after the treatment is completed. However, some of the chemotherapy agents used during treatment of testicular cancer may cause long-term side effects. These include **hearing loss**, nerve damage, and possible kidney or lung damage. Another potentially serious long-term complication is an increased risk of leukemia. This is a rare side effect as it occurs in less than 1% of testicular cancer patients who receive chemotherapy. Chemotherapy may also interfere with sperm production. This may be permanent for some, but many will regain their fertility within a few years.

Studies are ongoing to determine whether high doses of chemotherapy combined with stem-cell transplantation will prove effective in treating some patients with advanced testicular cancer. In this treatment, blood-forming cells called stem cells are taken from the patient (either from the bone marrow or filtered out of the patient's blood). These cells are kept frozen while high-dose chemotherapy is administered. After receiving the chemotherapy, the patient is given the stem cells through an infusion. This treatment enables the use of extra large doses of chemotherapy that might increase the cure rate for some testicular cancers.

Preferred treatment plans by stage of disease

Stage I: Stage I seminomas are normally treated with a radical inguinal orchiectomy followed by radiation treatment aimed at the lymph nodes. More than 95% of Stage I seminomas are cured through this method. Another treatment approach is treatment with a single dose of the chemotherapy drug, carboplatin, as an alternative to radiation therapy. Patients in this stage can experience relapse of the disease as long five years or more after orchiectomy. Therefore, follow-up surveillance is strongly recommended. Current recommendations regarding follow-up include a history and physical examination with measurement of tumor markers every three to four months in the first year, every six months in the second year and then annually after the second year. For those patients not undergoing radiation therapy, more intense follow-up is currently recommended. Stage I non-seminomas are also highly curable with surgery, followed by one of three options. These options include the performance of a retroperitoneal lymph node dissection, two cycles of chemotherapy, or careful observation for several years.

Stage II: Stage II seminomas and non-seminomas are cured in 90–95% of the cases. For the purposes of treatment, stage II testicular cancers are classified as either bulky or nonbulky. Nonbulky seminomas (no lymph nodes can be felt in the abdomen) are treated

with an orchiectomy followed by radiation to the lymph nodes. Men with bulky seminomas have surgery, which is followed by a course of chemotherapy. Nonbulky Stage II non-seminomas are treated with surgery and lymph node removal, with possible chemotherapy. Men with bulky disease have surgery followed by chemotherapy.

Stage III: Stage III seminomas and non-seminomas are treated with surgery followed by chemotherapy. Those who are not cured may be eligible to participate in clinical trials of other chemotherapy agents. Virtually all patients with advanced seminoma, approximately 80% of patients, are cured after receiving chemotherapy with the drug cisplatin.

Recurrent: Treatment of recurrent testicular cancer is dependent upon the initial stage and the treatment given. This might include further surgery and chemotherapy. Many men whose disease comes back after chemotherapy are treated with high-dose chemotherapy followed by autologous stem cell transplantation.

Prognosis

The overall five-year survival rate for testicular cancer is 95%, making testicular cancer one of the most curable forms of cancer. According to the American Cancer Society, almost 200,000 American men have survived testicular cancer. When the cancer is detected before it has had the time to spread outside of the testicle the five-year survival rate is 99%. The survival rates for testicular cancers that have spread to the local lymph nodes and for those cancers that have spread beyond the lymph nodes in the immediate area are 96% and 71% respectively. The key is early diagnosis. Delay in diagnosis results in the patient's presentation in a more advanced stage of the disease at the time of diagnosis.

Prevention

The main risk factors associated with testicular cancer—cryptorchidism, family history of the disease, and being Caucasian—are unavoidable since they are present at birth. In addition, many men diagnosed with the disease have no known risk factors. Because of these reasons, it is not possible to prevent most incidences of testicular cancer.

Special concerns

For many men, testicles are symbolic of manhood, and the removal of one can lead to embarrassment, or fear about a partner's reaction. Indeed, after surgical removal, the affected side of the scrotum does look and feel empty. To correct this, a patient can have a testicular prosthesis implanted in his scrotum. This prosthesis looks and feels like a real testicle, and the surgical procedure usually leaves only a small scar.

Testicular self-examination

Definition

A testicular self-examination (TSE) is the procedure by which a man checks the appearance and consistency of his testes.

Purpose

Most testicular cancers are first noticed by the man himself. Men should do a TSE every month to find out if the testes contain any suspicious lumps or other irregularities, which could be signs of cancer or infection.

Precautions

No special precautions are necessary.

Description

A TSE should take place during a warm shower or bath, when the skin is warm, wet, and soapy. The man needs to step out of the tub so that he is in front of a mirror. The heat from the tub or shower will relax the scrotum (sac containing the testes) and the skin will be softer and thinner, making it easier to feel a lump. It is important that the exam be done very gently.

The man should stand facing his mirror and look for swelling on the scrotum. Using both hands, the scrotum should be gently lifted so that the area underneath can be checked.

The next step is examination by hand. The index and middle fingers should be placed under each testicle, with the thumbs on top. The testes should be examined one at a time. The man should roll each testicle between his fingers and thumbs. He should feel for lumps of any size (even as small as a pea) particularly on the front or side of each testicle. He should also look for soreness or irregularities. Next, the epididymis and vas deferens, located on the top and back of the testes, should be felt. This area feels like a cord, and should not be tender.

Results

It is normal for one testicle to be larger than the other is, and for them to hang at different levels; but the size should stay the same from one month to the next. The testes should be free from lumps, **pain**, irregularities and swelling.

Abnormal results

A TSE is considered abnormal if any swelling, tenderness, lumps, or irregularities are found. Hard, unmoving lumps are abnormal, even if they are painless. A lump could be a sign of an infection or a cancerous tumor. A change in testicle size from one month to the next is also abnormal. A feeling of heaviness in the scrotum is another abnormal sign. If any abnormality is found, a man is encouraged to check with his doctor as soon as possible because **testicular cancer** is highly curable if found early.

KEY TERMS

Epididymis—A tube in the back of the testes that transports sperm.

Scrotum—The pouch containing the testes.

Testes—Egg-shaped male gonads located in the scrotum. Testes is the plural form of testis, which is a testicle.

Vas deferens—A tube that is a continuation of the epididymis. This tube transports sperm from the testis to the prostatic urethra.

Testicular surgery

Definition

Testicular surgery is any surgical operation on the testicles.

Purpose

Testicular surgery is used primarily to correct developmental defects, treat infection or **trauma**, and treat cancer of the testes.

Precautions

Testicular surgery, a group of surgical operations performed on the testicles, is considered major surgery. In all cases, except when the testes are being removed, care must be taken not to damage any of the nerves and blood vessels supplying the testes and associated organs.

Description

Testicular surgery is commonly performed for the following reasons: to reposition **undescended testes** (**orchiopexy**); to correct **testicular torsion**; to treat **testicular cancer**, which may involve removal of the testicles (castration) or the testes (orchiectomy); to treat traumatic injuries of the testicles; and to correct intersex states.

Undescended testes

Undescended testes are testes that have not dropped into the scrotum. During the fetal stage of development, the testes are not in the scrotum, but in the body. As male children age, the testes descend from the body to the scrotum for proper maturation and function. Undescended testes must be treated with surgery. There are two types of undescended testes, ectopic and cryptorchid. Ectopic testes are outside the normal route of descent. Cryptorchid testes are in the proper route of descent, but descent has been stopped before the testes reached the scrotum. The treatment for undescended testes is a surgical operation called orchiopexy, in which an incision allows the surgeon to reach the testes and pull them down into the scrotum. This operation is best done between the ages of one and two; otherwise, the testes are unlikely to mature normally. If the patient has one normal testis and one poorly developed testis, the undeveloped testis is usually removed.

Testicular torsion

Testicular torsion is a developmental defect in the tissues of the scrotum that allows the testes to rotate within the scrotum. This results in the blood vessels around other tubes in the scrotum to become wrapped around each other, resulting in blood supply to the testes bring cut off. Torsion disease is seen in young boys. **Pain**, nausea, and scrotal swelling are the main symptoms. When torsion is suspected, immediate surgery is recommended. An incision is made in the scrotum, and the blood vessels and other tissues are untangled. During surgery, the testes are examined to determine their condition. If they have received enough blood to remain viable, the testes are surgically attached to scrotal tissue to prevent twisting from recurring. If the testes do not regain a healthy pink color after the blood vessels have been untangled, then it is best to remove the testes. The lack of a pink color indicates that the testes have been without blood for too long a time period, and are dead tissue. Unless removed, they will turn necrotic and cause further harm to the body. Usually, testicular torsion occurs in only one testis. However, because the other testicle has similar anatomy, it too is subject to torsion. During surgery, the other testicle is attached to scrotal tissue to prevent torsion from occurring.

Cancer

Carcinoma of the testes is the medical term for cancer of the testicles. For males between ages 20–35, carcinoma of the testes is the second most common cancer. It accounts for 1–2% of all cancers in all males. There are many kinds of cancer that can affect the testes. A mass of tissue that is suspected to be cancer should be removed surgically. It is recommended that a biopsy not be performed, but that the physician proceed directly to surgery. Biopsies have not proven to be better at diagnosing cancer of the testicles than exploratory surgery. If the presence of cancer is confirmed during exploratory surgery, surgical excision of the cancer can be performed immediately.

The approach to the cancer during the operation depends on the location of the tissue mass. The two main approaches are through the scrotum and through the groin (inguinal region). The amount of tissue removed is variable and depends on the amount of cancerous tissue and the location. If a solid lesion is confirmed within a testis, a radical orchiectomy should be performed. A radical orchiectomy is a complete removal of one or both testes and associated lymphatic tissue. Other tumors allow partial removal of a testis. After surgery, the tumor is examined to determine the type of tumor for use as a guide in followup therapy.

Castration is the surgical removal of the testicles. Castration is performed as a cancer therapy, to reduce the amount of testosterone being produced, and as part of treatment for **prostate cancer**. In castration, an incision is made through one or both sides of the scrotum, depending on whether one or both testicles are being removed.

Trauma

Traumatic injuries to the testes may involve penetrating gunshot or knife **wounds**; explosions and other industrial accidents; and athletic injuries. Dislocation of the testes is a potential complication of blunt trauma to the abdomen, which commonly occurs in automobile or motorcycle accidents. A dislocated

KEY TERMS

Biopsy—Removing tissue to test it for disease.

Lesion—An injury in the body tissue, such as a wound, sore, rash, or boil.

Orchiectomy—Surgical removal of one or both testes.

Orchiopexy—Surgical fixation of one or both testes.

Testes—The pair of male reproductive glands enclosed in the scrotum that produce the male sex hormone testosterone and the spermatozoa. The singular form is testis.

Testicles—The testes along with their enclosing structures.

testis can usually be identified by either **ultrasound** or CT scans of the patient's pelvis.

Intersex states

Intersex states are a group of developmental diseases in which the patient has parts of both male and female genitalia. In testicular feminization syndrome, the patient appears to be a female and will have female genitalia but has internal testes. The internal testes are undescended. Genetic studies show that the person was to be a male. This form of intersex is also called male pseudohermaphroditism. There are a number of different causes of this condition. These patients produce the male hormone testosterone. Treatment consists of surgical removal of the internal testes, and the administration of the hormone estrogen, which produces female characteristics. Failure to remove the testes is associated with a higher rate of cancer in these patients.

Preparation

About one hour before receiving general **anesthesia**, the patient will get a shot that dries up internal fluids and makes him sleepy. Presurgical counseling is often recommended for patients whose reproductive abilities will be compromised by their surgeries.

Aftercare

A patient who has had a testicle removed should visit his physician once a month for the first year and every other month for the second year, with periodic followups thereafter.

Risks

Testicular surgery, like any major surgery, can have postoperative complications. These complications include internal bleeding and wound infection, as well as adverse reactions to anesthesia. About 10–15% of patients develop fertility problems.

There is growing evidence that men who have had an orchiectomy followed by external beam **radiation therapy** have a significantly increased risk of dying from **heart disease** or a second cancer.

Results

Undescended testes are pulled down into their correct position and mature normally. In testicular torsion, the affected testis either regains its healthy pink color and is attached to the surrounding tissue with sutures, or it is removed along with any dead tissue surrounding it. (So long as only one testis is removed, sexual function and fertility will not be affected.) Successful surgery for cancer results in the removal of malignant tissue.

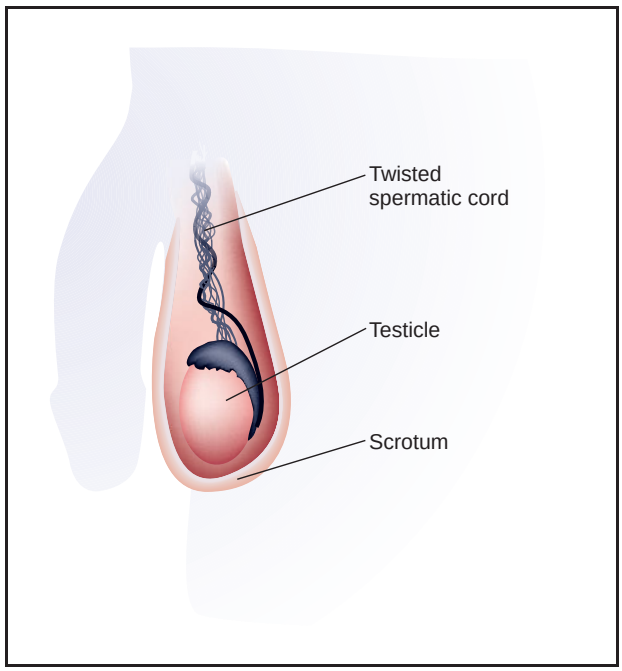
Testicular torsion

Definition

Testicular torsion is the twisting of a testis (testicle) on its connection, the spermatic cord. Testicular torsion is a medical emergency requiring immediate attention.



A rare condition, testicular torsion occurs when the spermatic cord is twisted and cuts off the blood supply to the testicle. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

KEY TERMS

Orchiopexy—The surgical securing of the testis to prevent torsion.

Scrotum—The bag of skin below the penis that contains the testes.

Demographics

About 70% of cases of testicular torsion occur prenatally while the infant is still in the uterus. Prenatal testicular torsion is associated with high birth weight. Of the remaining 30%, peak incidence is in boys ages 13–14, and most cases occur in males under age 25 years.

Description

The testes are suspended in the scrotum by the spermatic cord, a single bundle of tissues that also carries the blood supply to and from the testes. If a testicle rotates, the bundle kinks, and the blood supply is shut off. The resulting situation is an emergency because the testis will die within hours if the blood supply is not restored. Testicular torsion is the most common cause for loss of a testicle.

Causes and symptoms

Some testes hang in such a way that they twist more easily than others. Nearly all torsions happen either prenatally or to adolescent males between the ages of 12 and 18 because their testes enlarge by a factor of 5–6 during **puberty**. A larger testis is more likely to twist. Torsion can also occur in a newborn.

Symptoms of testicular torsion are sudden severe **pain** in the scrotum, swelling, **nausea and vomiting**.

Diagnosis

Tests

Swift diagnosis is essential to save the testicle. The physician examines the scrotum and may order a **urinalysis** to look for white blood cells. A nuclear scan of the scrotum may be performed. In this procedure, a tiny amount of radioactive fluid is injected into the blood and detected as it flows through the scrotum and testicles. Torsion is indicated if the radioactive fluid does not flow through the sore testis. **Ultrasound** scan accompanied by a contrast agent can also be used to diagnose testicular torsion.

Treatment

Surgery must be performed within 24 hours to ensure the health of the affected testis. During the procedure, the surgeon untwists the cord and secures the testis in place so that it cannot rotate again. The other testicle should also be secured to deter future testicular torsion. This procedure is called **orchiopexy**.

Prognosis

If the torsion is relieved within 6 hours of the onset of pain, testis will recover normal blood flow and function in more than 90% of cases. If surgery occurs 6–12 hours after the pain begins, the testicle can be saved in 20–50% of cases. If surgery is delayed 24 hours or more, there is little chance (0–10% that the testicle can be saved.

Prevention

Torsion of the unaffected testis is prevented by securing it during the surgery to correct the twisted testis.

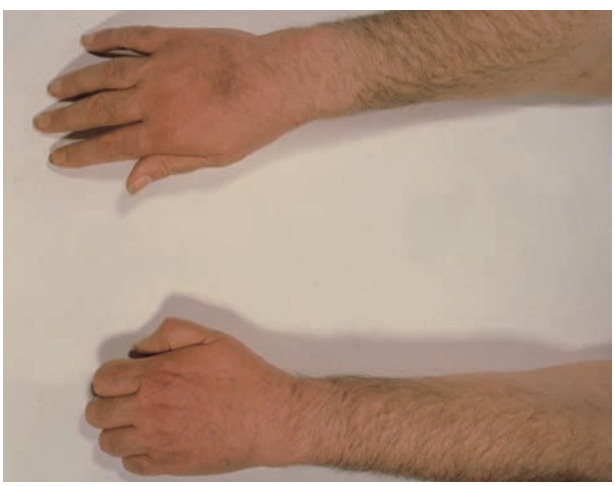
Tetanus

Definition

Tetanus is a rare and often fatal bacterial disease of the central nervous system (brain and spinal cord). It is sometimes called lockjaw, because the first symptom is often a tightening or locking of the jaw muscles that prevent opening the mouth or swallowing.

Description

Tetanus is an acute disease caused by a toxin formed and secreted by a bacterium (such toxins are called exotoxins). For tetanus the bacterium is *Clostridium tetani*. In humans, the toxin affects the central nervous system, causing painful contractions, stiffness, rigidity, convulsive spasms, and **paralysis** of the skeletal muscles, usually beginning in the jaw and neck and then generalizing throughout the body. Without treatment, it has a fatality rate of about 25%. With treatment, the death rate drops to 15%.



One characteristic of tetanus bacillus is the recurrent contracture of a muscle. Here, the patient's left hand is affected. *(Custom Medical Stock Photo, Inc.)*

Tetanus is not contagious. In fact, it is the only vaccine-preventable **infectious disease** that cannot be transmitted directly from one person to the next. It is transmitted by spores. *C. tetani* is a spore-forming bacterium, and its spores are found in the soil, and in animal and human intestines. It is these spores that typically infect a person by way of a wound.

Origins

Clinical descriptions of tetanus date back to the fifth century BCE. In 1884, it was first shown that tetanus could be produced in animals by injecting them with soil samples or with pus from a human victim. Both common soil samples and pus from an infected person contained the bacterium that causes tetanus. Five years later, Japanese physician and bacteriologist Shibasaburo Kitasato first isolated *C. tetani* from a human victim, demonstrated that it could produce disease in animals, and reported that specific antibodies could neutralize the toxin. In 1897, French microbiologist Edmond Nocard showed that tetanus antitoxin could induce passive immunity in humans (in passive immunity, a person receives antibodies rather than making them), and this method was used for both prevention and treatment during World War I. Inactivation of the tetanus toxin with formaldehyde led to the 1924 development of a preventive inoculation (tetanus toxoid) by French student Pierre Descombey (working under his instructor, veterinarian and biologist Gaston Ramon), and this vaccine was used widely during World War II.

Risk factors

The major risk factor for tetanus is a wound that is contaminated with *C. tetani* when it occurs in people who have not been vaccinated or have not received 10-year boosters. Newborns whose mothers have not been vaccinated are also at higher risk for tetanus. Heroin users, especially those who inject the drug subcutaneously (under the skin), face an increased chance of experiencing tetanus, because quinine is added to heroin, and quinine can be contaminated with *C. tetani*.

Demographics

Tetanus occurs throughout the world but is most common in densely populated, hot, damp regions

where the soil is rich in organic matter. Neonatal (newborn) tetanus, although extremely rare in the developed world, is common in some developing countries, causing about 60,000 infant deaths each year, according to the Child Health Epidemiology Reference Group. The World Health Organization (WHO) places the number closer to 200,000 per year. This compares to the 1988 WHO estimate of 787,000 infant deaths due to neonatal tetanus.

Causes and symptoms

Causes

C. tetani spores usually enter the body through a cut or wound that is exposed to contaminated soil, dust, manure, or human feces. Tetanus most often results from a deep puncture wound, because *C. tetani* spores germinate under low-oxygen (anaerobic) conditions within the body. Puncture **wounds** provide just those conditions. The bacterium produces two exotoxins—tetanolysin and tetanospasmin—that circulate through the blood and lymph. The function of tetanolysin is unclear, but tetanospasmin is one of the most potent known toxins. Tetanospasmin acts upon several sites within the brain and spinal cord. It interferes with the release of neurotransmitters by nerve cells (nerve cells use neurotransmitters to communicate), which prevents the transmission of inhibitory impulses and causes muscles to be incessantly stimulated. This results in continuous muscle contractions and spasms. The toxin can also cause seizures and affect the autonomic nervous system, which regulates such organs as the heart, stomach, and intestines.

Besides puncture wounds, tetanus can result from surgical wounds, **burns**, ear or dental infections, animal scratches or bites, abortion, and intravenous drug use. In recent years, minor wounds are becoming an increasingly common cause of tetanus, probably because severe injuries are more likely to be appropriately cleaned. Besides contaminated wounds, cases have also been reported in people with no known wound or medical condition. Neonatal tetanus usually results from infection of the unhealed umbilical stump—especially if the cord was cut with an unsterile instrument. This can occur in newborns who lack passive immunity, because their mothers have not been immunized and so did not pass on protective antibodies through the placenta.

Symptoms

Symptoms of tetanus usually appear about eight days after infection. Neonatal tetanus develops, on average, seven days after birth. In general, the further the injury from the central nervous system, the longer the incubation period, and the shorter the incubation period, the higher the risk of death.

About 80% of tetanus cases, including neonatal tetanus, are generalized (affecting the entire body), most often in a descending pattern beginning with lockjaw (trismus), which results in a teeth-gritting facial expression called the sardonic smile (risus sardonicus). This is followed by neck stiffness, difficulty swallowing, rigidity of abdominal muscles, and stiffness and uncontrollable spasms of other muscles throughout the body. Spasms may last several minutes and continue to occur for three to four weeks. Sometimes the convulsions are severe enough to break bones. Other symptoms include **fever**, sweating, elevated blood pressure, irritability, restlessness, loss of appetite, drooling, and periods of rapid heart rate.

Localized tetanus is an uncommon form of the disease that causes tingling and **pain** only at the wound site and contractions and spasms in nearby muscles. The incubation period ranges from 2–50 days following injury, although symptoms usually appear within 5–10 days. The contractions may persist for weeks before gradually subsiding. Although local tetanus sometimes becomes generalized, it is usually milder and only about 1% of cases are fatal.

Cephalic tetanus is a rare form of tetanus. It can result from a **head injury** or ear infection (**otitis media**) if the bacterium is present in the middle ear. Cephalic tetanus affects the cranial nerves, especially those of the face.

Diagnosis

Examination

Early diagnosis and treatment is crucial to recovery from tetanus. It is diagnosed entirely from clinical symptoms, such as **muscle spasms**, stiffness, and pain, and a medical history that reveals a lack of immunization.

Treatment

Tetanus is a life-threatening disease that requires immediate hospitalization, usually in an intensive care unit (ICU). The treatment begins with the thorough cleaning of the wound, and removal of dead tissue and foreign material. Tetanic spasms require supportive therapy and the maintenance of an adequate airway. Artificial respiration may be necessary for severe cases.

Drugs are also used. Tetanus immune globulin (TIG) is administered to help remove any unbound toxin. **Antibiotics** are administered to kill the bacteria, and antitoxin shots neutralize the toxin. **Muscle**

WWW.BOOKBAZ.IR

relaxants can help control spasms, and **barbiturates** are used for **sedation**. As soon as the patient is stable, immunization with tetanus toxoid is begun or continued. Because of the potency of the toxin, having tetanus does not confer future immunity.

Alternatives

Dietary fruits and vegetables and other nutrient sources may help boost immune response to the tetanus vaccine.

Prognosis

Without treatment, fatality rates from tetanus are 25%, and are higher for neonatal tetanus. With treatment, the overall fatality rate for tetanus is 15%. For those who survive, complete recovery from tetanus can take six weeks to several months.

Tetracyclines

Definition

Tetracyclines are antibiotic medicines that kill bacteria and prevent their spread.

Purpose

Tetracyclines are called "broad-spectrum" **antibiotics**, meaning they can be used to treat a variety of infections, such as **gonorrhea**, **Rocky Mountain spotted fever**, **anthrax**, **Lyme disease**, and the bacterium (*Helicobacter pylori*) that causes peptic **ulcers**.

These drugs are used to treat infections in the lungs, urinary system, and skin (**acne**), and to prevent the spread of meningococcal **meningitis**.

Tetracyclines will not prevent or cure colds, flu, or other infections caused by viruses.

Description

Available only by prescription, tetracyclines come in capsule, tablet, liquid, and injectable forms.

Examples of tetracyclines include tetracycline (Sumycin), minocycline (Minocin and Dynacub) and doxycycline (Doryx, Vibramycin).

Recommended dosage

The dose of this class of drugs depends on the reason for its use. It is usually taken orally on an empty stomach one hour before or two hours after a meal, two to four times daily. Taking it with a full glass of water is recommended.

Precautions

Patients should take antibiotics as prescribed for as long as they are prescribed. They should not stop taking them if symptoms improve.

These medicines work best when taken on an empty stomach, with a full glass of water.

Tetracyclines should be taken at least one hour before, or two hours after, eating dairy products like milk, cheese, yogurt or ice cream.

These drugs reduce the effectiveness of some birth control pills. A secondary method of **contraception** should also be used when taking them.

Tetracyclines can produce false blood or urine sugar test results in diabetics.

Taking old, outdated tetracyclines may produce kidney damage.

Tetracyclines can permanently discolor growing and developing teeth and should not be given to pregnant women or children under the age of eight.

People taking these drugs are more vulnerable to **sunburn** and should avoid exposure to direct sunlight or prolonged use of **tanning** equipment.

Patients who take tetracyclines for prolonged periods of time should have periodic blood counts and their liver and kidney functions monitored.

Over-the-counter products, **vitamins** and food supplements that contain **minerals** such as **calcium**, magnesium, iron or zinc may reduce the effectiveness of tetracyclines.

ALLERGIES. Anyone who has had unusual reactions to tetracyclines should let his or her physician know before taking the drugs again.

PREGNANCY. Pregnant women should not take tetracyclines during the last half of **pregnancy** as they may interfere with the development of baby's bones and teeth and can cause baby's adult teeth to be permanently discolored. The medicine can also cause liver problems in pregnant women.

BREASTFEEDING. Tetracyclines pass into breast milk and can affect nursing baby's teeth and bones, may make them more sensitive to sunlight, and increase the risk of **fungal infections** such as thrush.

OTHER MEDICAL CONDITIONS. Before using tetracyclines, people with any of these medical problems should make sure their physicians are aware of their conditions:

- liver disease
- kidney disease
- diabetes

Side effects

Most commonly, adverse effects from tetracyclines will be abdominal cramps and burning sensations, possibly with mild **diarrhea**.

Prolonged use of tetracyclines may produce chronic diarrhea from bacterial changes in the intestines.

These drugs may allow yeasts normally occurring in the body to produce infections in the mouth (thrush) and vagina (monilia).

These drugs may cause **dizziness**, nausea, blurred vision, headaches and **pain** behind the eyes that increases with coughing. These symptoms usually disappear after stopping the drugs.

Tetracyclines may affect the heart and produce **heart failure** in people who are hypersensitive to them.

These drugs may affect the skin, producing minor **rashes** and **itching** or even more serious skin conditions.

Interactions

Tetracyclines may increase the effectiveness of blood thinners, like warfarin (Coumadin). These

WWW.BOOKBAZ.IR

drugs increase the effectiveness of **digoxin** (Lanoxin) and may reduce the effectiveness of all penicillin drugs.

Minerals that may interact with, and reduce the effectiveness of, tetracyclines include:

- Calcium, in antacids and dietary supplements
- Aluminum in antacids
- Iron in foods, multivitamins and mineral supplements
- Magnesium in antacids, laxatives and vitamin-mineral supplements
- Zinc in multivitamins and over the counter remedies

Tetralogy of Fallot is a common syndrome of congenital heart defects. This condition, present in utero, is caused by the narrowing of the pulmonary artery and a hole between the ventricles. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Tetralogy of Fallot

Definition

Tetralogy of Fallot is a common syndrome of congenital heart defects.

Description

The heart is two pumps in one. The ventricle on the left side pumps blood full of oxygen through the body; the ventricle on the right side pumps the same blood through the pulmonary artery to the lungs to take up oxygen. The left ventricle operates at pressures about four times as high as the right ventricle. Blood is supposed to flow through one side, then the other.

Tetralogy of Fallot is a condition that is characterized by several congenital heart defects occurring at once. They include:

- ventricular septal defect (abnormal passageway between the right and left ventricles)
- displaced aorta
- narrowed pulmonary valve
- thickened right ventricle wall

Each defect acts in combination with the others to create a malfunction of the heart. The problem starts very early in the uterus with a narrowed pulmonary valve and a hole between the ventricles. This is not particularly a problem for a fetus because hardly any blood flows through the lungs until birth. It is only after birth that the defects pose a problem. The blood that is supposed to start flowing through the lungs cannot easily get there because of the narrowed valve; however, the hole between the ventricles remains open. Because of the opening between ventricles, much of the blood that comes back to the heart needing oxygen is sent out without being properly oxygenated. In addition, the right heart has to pump at the same pressure as the left side. Several changes follow. First, the baby turns blue (cyanotic) because of the deoxygenated blood that bypasses the lungs. Deoxygenated blood is darker and appears blue through the skin. Second, the right side of the heart (ventricle) hypertrophies (gets more muscular) from the extra **exercise** demanded of it. Next, the low oxygen causes the blood to get thicker and clot more easily. Clots in the veins can now pass through the hole in the heart and directly enter the aorta, where they can do much more damage than in the lungs—such as causing infarcts in the brain. In addition, these anomalies make the lining of the heart more susceptible to infection—endocarditis– which can damage valves and lead to blood **poisoning** (septicemia).

Causes and symptoms

Tetralogy of Fallot is a congenital defect with unknown causes.

KEY TERMS

Aorta—Main arterial trunk that moves blood from the heart to the arteries, which transport the blood throughout the body.

Cyanosis—Blue-colored skin due to oxygen-deficient blood.

Endocarditis—Inflammation of the lining of the heart.

Infarct—Death of tissue due to shutting off the blood supply.

Septicemia—Blood poisoning.

Systemic circulation—Through the body, as opposed to "pulmonary"—through the lungs.

Ventricles—The muscular chambers of the heart that do the pumping.

Babies with tetralogy of Fallot are blue at birth (**cyanosis**). Sometimes the blue color appears only when they cry. They also have detectable **heart murmurs**. Infants with mild forms can have surgery postponed until they are older. Infants with more severe symptoms often have attacks of worsened cyanosis. During attacks, they turn very blue, have **shortness of breath**, and can faint. This usually occurs during heightened activity, such as crying.

Diagnosis

A complete evaluation of the circulation is required, including testing the blood for its oxygen content; **ultrasound**; and x rays of the heart accompanied by a contrast agent to determine the amount of blood flowing in the wrong direction. A search for other **birth defects** is also necessary, because they tend to happen together.

Treatment

Correction of the defects is done through surgery. Surgery must be carefully timed with attention to the progression of the disease process, the size of the infant, and the size of the various defects. There are temporary surgical procedures that can prolong the time before corrective surgery while the baby grows larger and stronger.

During surgery, the pulmonary valve is widened, the **ventricular septal defect** is closed, and any interim corrections removed.

Prognosis

Surgical correction has a high rate of success, returning the child to near–normal health.

Thalassemia

Definition

Thalassemia is a group of inherited disorders characterized by reduced or absent amounts of hemoglobin, the oxygen–carrying protein inside red blood cells. There are two basic groups of thalassemia disorders: alpha thalassemia and beta thalassemia. These conditions cause varying degrees of anemia, which can range from insignificant to life threatening.

Demographics

The thalassemias are among the most common genetic diseases worldwide. Both alpha and beta thalassemia have been described in individuals of almost every ancestry, but the conditions are more common among certain ethnic groups.

Beta thalassemia trait is seen most commonly in people with the following ancestry: Mediterranean (including North African, and particularly Italian and Greek), Middle Eastern, Indian, African, Chinese, and Southeast Asian (including Vietnamese, Laotian, Thai, Singaporean, Filipino, Cambodian, Malaysian, Burmese, and Indonesian). Alpha thalassemia trait is seen with increased frequency in the same ethnic groups; however, there are different types of alpha thalassemia traits within these populations. The frequency of hemoglobin H disease and alpha thalassemia major depends on the type of alpha thalassemia trait. The populations in which alpha thalassemia diseases are most common include Southeast Asians and Chinese (particularly Southern Chinese).

It is difficult to obtain accurate prevalence figures for various types of thalassemia within different populations. This difficulty arises because of testing limitations in determining exact genetic diagnoses, as well as the fact that many studies have focused on small, biased hospital populations. Internationally it is estimated that 15 million people have clinical symptoms of thalassemia. However, the number of people carrying the genetic mutation for the trait appears to be much higher. One study

WWW.BOOKBAZ.IR

estimated that in India alone, 30 million people carried a genetic mutation for one of the thalassemias.

Determining prevalence figures for alpha thalassemia is even more difficult because of limitations in diagnostic testing. Two studies reflect prevalence figures that can be helpful counseling families and determining who to screen for beta thalassemia. Between 1990 and 1996, the state of California screened more than 3.1 million infants born in the state for beta thalassemia. Approximately one in 114,000 infants had beta thalassemia major, with prevalence rates being highest among Asian Indians (about one in 4,000), Southeast Asians (about one in 10,000), and Middle Easterners (about one in 7,000). Another type of beta thalassemia disease, E/beta thalassemia, was represented in approximately one in 110,000 births, all of which occurred in families of Southeast Asian ancestry. Among Southeast Asians, the prevalence of E/beta thalassemia was approximately one in 2,600 births. This result is in keeping with the observation that hemoglobin E trait carrier rates are relatively high within the Southeast Asian population: 16% in a study of 768 immigrants to California, and up to 25% in some specific Southeast Asian populations such as Cambodians. While these California studies address some of the limitations of earlier population studies, the pattern observed in California is expected to be different in other areas of the United States and the world. For example, Italians are underrepresented in this population when compared to the population of the East Coast of the United States.

Description

All types of thalassemias are considered quantitative diseases of hemoglobin, because the quantity of hemoglobin produced is reduced or absent. Usual adult hemoglobin is made up of three components: alpha globin, beta globin, and heme. Thalassemias are classified according to the globin that is affected, hence the names *alpha* and *beta* thalassemia. Although both classes of thalassemia affect the same protein, the alpha and beta thalassemias are distinct diseases that affect the body in different ways.

Beta thalassemia

Beta thalassemia may be the best–known type of thalassemia and is also called Cooley's anemia. It is caused by a change in the gene for the beta globin component of hemoglobin. Beta thalassemia causes variable anemia that can range from moderate to severe, depending in part on the exact genetic change underlying the disease. Beta thalassemia can be classified based on clinical symptoms. Beta thalassemia major usually causes severe anemia that can occur within months after birth. If left untreated, severe anemia can result in insufficient growth and development, as well as other common physical complications that can lead to a dramatically decreased life expectancy. In developed countries, beta thalassemia usually is identified by screening in the newborn period before symptoms have developed. Children who are identified early can be started on ongoing blood **transfusion** therapy as needed. Although transfusion therapy prevents many of the complications of severe anemia, the body is unable to eliminate the excess iron contained in the transfused blood. Over time, the excess iron deposits in tissues and organs, resulting in damage and organ failure. Another medication must be administered to help the body eliminate the excess iron and prevent iron–overload complications. Beta thalassemia intermedia is a term used to describe the disease in individuals who have moderate anemia that requires blood transfusions only intermittently, if at all.

Alpha thalassemia

Alpha thalassemia is the result of changes in the genes for the alpha globin component of hemoglobin. There are two main types of alpha thalassemia disease: hemoglobin H disease and alpha thalassemia major. The two diseases are quite different from beta thalassemia as well as from one another. Individuals with hemoglobin H disease can experience events of hemolytic anemia—anemia caused by the rapid breakdown of red blood cells. These events are thought to be triggered by various environmental causes, such as infection and/or exposure to certain chemicals. Hemoglobin H disease is in most cases milder than beta thalassemia. It does not generally require transfusion therapy. Alpha thalassemia major is a very serious disease that results in severe anemia that begins even before birth. Most affected babies do not survive to be born, or they die shortly after birth.

Unaffected carriers of all types of thalassemia traits do not experience health problems. In fact, the thalassemia trait is protective against **malaria**, a disease caused by blood–borne parasites transmitted through mosquito bites. According to a widely accepted theory, most genetic changes (mutations) that cause thalassemia occurred multiple generations ago. Coincidentally, these mutations increased the likelihood that carriers would survive malaria infection. Survivors passed the mutation onto their offspring, and the trait became established throughout areas where malaria is common. As populations migrated, so did the thalassemia traits.

Causes and symptoms

Genetics

Humans normally make several types of the oxygen–carrying protein hemoglobin. An individual's stage in

development determines whether he or she makes primarily embryonic, fetal, or adult hemoglobins. All types of hemoglobin are made of three components: heme, alpha (or alpha–like) globin, and beta (or beta–like) globin. All types of thalassemia are caused by changes in either the alpha or beta–globin gene. These changes cause the production of little or no globin. The thalassemias are, therefore, considered quantitative hemoglobin diseases. All types of thalassemias are recessively inherited, meaning that a genetic change must be inherited from both the mother and the father in order for the offspring to show symptoms of the disease. The severity of the disease is influenced by the exact thalassemia mutations inherited, as well as other genetic and environmental factors. There are rare exceptions, notably with beta thalassemia, where globin gene mutations exhibit a dominant pattern of inheritance in which only one gene needs to be altered in order to see disease symptoms.

BETA THALASSEMIA. Most individuals have two normal copies of the beta globin gene, which is located on chromosome 11 and makes the beta globin component of normal adult hemoglobin, hemoglobin A. There are approximately 100 genetic mutations that have been described that cause beta thalassemia, designated as either beta0 or beta+ mutations. No beta globin is produced with a beta0 mutation, and only a small fraction of the normal amount of beta globin is produced with a beta+ mutation.

When an individual has one normal beta globin gene and one with a beta thalassemia mutation, he or she is said to carry the beta thalassemia trait. Beta thalassemia trait, like other hemoglobin traits, is protective against malaria infection. Trait status is generally thought not to cause health problems, although some women with beta thalassemia trait may have an increased tendency toward anemia during **pregnancy**.

When two members of a couple carry the beta thalassemia trait, there is a 25% chance that each of their children will inherit beta thalassemia disease by inheriting two beta thalassemia mutations, one from each parent. The clinical severity of the beta thalassemia disease—whether an individual has beta thalassemia intermedia or beta thalassemia major—will depend largely on whether the mutations inherited are beta0 thalassemia or beta+ thalassemia mutations. Two beta0 mutations generally lead to beta thalassemia major, and two beta+ thalassemia mutations generally lead to beta thalassemia intermedia. Inheritance of one beta0 and one beta+ thalassemia mutation tends to be less predictable.

Although relatively uncommon, there are other thalassemia–like mutations that can affect the beta globin gene. Hemoglobin E is the result of a substitution of a single nucleotide. This change results in structurally altered hemoglobin that is produced in decreased amounts. Therefore, hemoglobin E is unique in that it is both a quantitative (i.e., thalassemia–like) and qualitative trait. When co–inherited with a beta thalassemia trait, it causes a disease that is almost indistinguishable from beta thalassemia disease. Large deletions around and including the beta globin gene can lead to delta/beta thalassemia or hereditary persistence of fetal hemoglobin (HPFH). Interestingly, delta/beta thalassemia trait behaves very similarly to beta thalassemia trait in its clinical manifestations. However, HPFH trait does not tend to cause hemoglobin disease when co–inherited with a second thalassemia or other beta globin mutation.

ALPHA THALASSEMIA. Most individuals have four normal copies of the alpha globin gene, two copies on each chromosome 16. These genes make the alpha globin component of normal adult hemoglobin, which is called hemoglobin A. Alpha globin is also a component of fetal hemoglobin and the other major adult hemoglobin called hemoglobin A2. Mutations of the alpha globin genes usually involve deletions of the gene, resulting in absent production of alpha globin. Since there are four genes (instead of the usual two) to consider when looking at alpha globin gene inheritance, several alpha globin types are possible.

Absence of one alpha globin gene leads to a condition known as silent alpha thalassemia trait. This condition causes no health problems and can be detected only by special **genetic testing**. Alpha thalassemia trait occurs when two alpha globin genes are missing. This change can occur in two ways. The genes may be deleted from the same chromosome, causing the 'cis' type of alpha thalassemia trait. Alternately, they may be deleted from different chromosomes, causing the 'trans' type of alpha thalassemia trait. In both instances, there are no associated health problems, although the trait status may be detected by more routine blood screening.

Hemoglobin H disease results from the deletion of three alpha globin genes, such that there is only one functioning gene. Typically, this change occurs when one parent carries the silent alpha thalassemia trait, and the other parent carries the 'cis' type of the alpha thalassemia trait. In this situation, there is a 25% chance for hemoglobin H disease in each of such a couple's children.

Hemoglobin H disease–like symptoms also can be a part of a unique condition called alpha thalassemia mental retardation syndrome. Alpha thalassemia mental retardation syndrome can be caused by a deletion of a significant amount of chromosome 16,

WWW.BOOKBAZ.IR

affecting the alpha globin genes. This condition is usually not inherited, but rather occurs sporadically in the affected individual. Affected individuals have mild hemoglobin H disease, mild–to–moderate intellectual disabilities (ID), and characteristic facial features. This syndrome can also occur as a sex–linked form in which a mutation is inherited in a particular gene on the X–chromosome. This gene influences alpha globin production, as well as various other developmental processes. Individuals affected with this form of the syndrome tend to have more severe ID, delayed development, nearly absent speech, characteristic facial features, and genital–urinary abnormalities. The remaining discussion will focus only on aspects of hemoglobin H disease.

Alpha thalassemia major results from the deletion of all four alpha globin genes, such that there are no functioning alpha globin genes. This can occur when both parents carry the 'cis' type of the alpha thalassemia trait. In this situation, there is a 25% chance for alpha thalassemia major in each of such a couple's children.

Symptoms

BETA THALASSEMIA. Beta thalassemia major is characterized by severe anemia that can begin months after birth. In the United States and other developed countries, beta thalassemia is identified and treated early and effectively. Therefore, the following discussion of symptoms applies primarily to affected individuals in the past and in some underdeveloped countries now. If untreated, beta thalassemia major can lead to severe lethargy, paleness, and delays in growth and development. The body attempts to compensate by producing more blood, which is made inside bone marrow. However, this process is ineffective without the needed genetic instructions to make enough functioning hemoglobin. Instead, obvious bone expansion and changes occur that cause characteristic facial and other changes in appearance, as well as increased risk of **fractures**. Severe anemia taxes other organs in the body, such as the heart, spleen, and liver, which must work harder than usual. This can lead to **heart failure**, as well as enlargement and other problems of the liver and spleen. When untreated, beta thalassemia major generally results in childhood death, usually due to heart failure.

In developed countries diagnosis usually is made early, often before symptoms have appeared. This allows for treatment with blood transfusion therapy, which can prevent most of the complications of the severe anemia caused by beta thalassemia major. Individuals with beta thalassemia intermedia have a more moderate anemia that may require treatment with transfusion intermittently only, such as when infections occur and **stress** the body. As a person with beta thalassemia intermedia gets older, however, the need for blood transfusions may increase to the point that they are required on a regular basis. When this occurs their disease becomes more similar to beta thalassemia major. Other genetic and environmental factors can influence the course of the disease as well. For example, co–inheritance of one or two alpha thalassemia mutations can tend to ameliorate some of the symptoms of beta thalassemia disease, which result in part from an imbalance in the amount of alpha–and beta–globin present in the red blood cells.

HEMOGLOBIN H DISEASE. Absence of three alpha globin genes causes an imbalance of alpha and beta globin proteins in the red blood cells. The excess beta globin proteins tend to come together to form hemoglobin H, which is unable to release oxygen to the tissues. In addition, hemoglobin H tends to precipitate out in the cells, causing damage to the red blood cell membrane. When affected individuals are exposed to certain drugs and chemicals known to make the membrane more fragile, the cells are thought to become vulnerable to break down in large numbers, a complication called **hemolytic anemia**. **Fever** and infection are also considered triggers of hemolytic anemia in hemoglobin H disease. This disease can result in **fatigue**, paleness, and a yellow discoloration of the skin and whites of eyes called **jaundice**. Usually, the anemia is mild enough not to require treatment. Severe anemia events may require blood transfusion, and are usually accompanied by such other symptoms as dark feces or urine and abdominal or back **pain**. These events are uncommon in hemoglobin H disease, although they occur more frequently in a more serious type of hemoglobin H disease called hemoglobin H/Constant Spring disease. Individuals effected with this type of hemoglobin H disease are also more likely to have enlargement of and other problems with the spleen.

ALPHA THALASSEMIA MAJOR. Because alpha globin is a necessary component of all major hemoglobins and some minor hemoglobins, absence of all functioning alpha globin genes leads to serious medical consequences that begin even before birth. Affected fetuses develop severe anemia as early as the first trimester of pregnancy. The placenta, heart, liver, spleen, and adrenal glands may all become enlarged. Fluid can begin collecting throughout the body as early as the start of the second trimester, causing damage to developing tissues and organs. Growth retardation is

also common. Affected fetuses usually miscarry or die shortly after birth. In addition, women carrying affected fetuses are at increased risk of developing complications of pregnancy and delivery. Up to 80% of such women develop toxemia, a disturbance of metabolism that can potentially lead to convulsions and **coma**. Other maternal complications include premature delivery and increased rates of delivery by **cesarean section**, as well as hemorrhage after delivery.

Diagnosis

Diagnosis of thalassemia can occur under various circumstances and at various ages. Several states offer thalassemia screening as part of the usual battery of blood tests done for newborns. This allows for early identification and treatment. Thalassemia can be identified before birth through prenatal diagnosis. **Chorionic villus sampling** (CVS) can be offered as early as 10 weeks of pregnancy and involves removing a sample of the placenta made by the baby and testing the cells. CVS carries a risk of causing a **miscarriage** that is between 0.5–1%. **Amniocentesis** is generally offered between 15 and 22 weeks of pregnancy, but can sometimes be offered earlier. Two to three tablespoons of the fluid surrounding the baby is removed. This fluid contains fetal cells that can be tested. The risk of miscarriage associated with amniocentesis ranges from 0.33–0.5%. Pregnant woman and couples may choose prenatal testing in order to prepare for the birth of a baby that may have thalassemia. Alternately, knowing the diagnosis during pregnancy allows for the option of pregnancy termination. Preimplantation genetic diagnosis (PGD) is a relatively new technique that involves in–vitro fertilization followed by genetic testing of one cell from each developing embryo. Only the embryos unaffected by genetic disease are transferred back into the uterus.

Thalassemia may be suspected if an individual shows signs that are suggestive of the disease. In all cases, however, laboratory diagnosis is essential to confirm the exact diagnosis and to allow for the provision of accurate **genetic counseling** about recurrence risks and testing options for parents and affected individuals. Screening is likewise recommended to determine trait status for individuals of high–risk ethnic groups.

Tests

The following tests are used to screen for thalassemia disease and/or trait:

- complete blood count
- hemoglobin electrophoresis with quantitative hemoglobin A2 and hemoglobin F
- free erythrocyte–protoporphyrin (or ferritin or other studies of serum iron levels)

A **complete blood count** (CBC) will identify low levels of hemoglobin, small red blood cells, and other red blood cell abnormalities that are characteristic of a thalassemia diagnosis. Since thalassemia trait can sometimes be difficult to distinguish from iron deficiency, tests to evaluate iron levels are important. A **hemoglobin electrophoresis** is a test that can help identify the types and quantities of hemoglobin made by an individual. This test uses an electric field applied across a slab of gel–like material. Hemoglobins migrate through this gel at various rates and to specific locations, depending on their size, shape, and electrical charge. Isoelectric focusing and high–performance liquid chromatography (HPLC) use similar principles to separate hemoglobins and can be used instead of or in various combinations with hemoglobin electrophoresis to determine the types and quantities of hemoglobin present. Hemoglobin electrophoresis results are usually within the normal range for all types of alpha thalassemia. However, hemoglobin A2 levels and sometimes hemoglobin F levels are elevated when beta thalassemia disease or trait is present. Hemoglobin electrophoresis can also detect structurally abnormal hemoglobins that may be co–inherited with a thalassemia trait to cause thalassemia disease (i.e., hemoglobin E) or other types of hemoglobin disease (i.e., sickle hemoglobin). Sometimes DNA testing is needed in addition to the screening tests. Such testing can be performed to help confirm the diagnosis and establish the exact genetic type of thalassemia.

Treatment

Beta thalassemia

Individuals with beta thalassemia major receive regular blood transfusions, usually on a monthly basis. Transfusions help prevent severe anemia and allow for more normal growth and development. Transfusion therapy does have limitations, however. Individuals can develop reactions to certain proteins in the blood (a transfusion reaction). This can make locating appropriately matched donor blood more difficult. Although blood supplies in the United States are very safe, particularly relative to the past and to other areas of the world, there remains an increased risk of exposure to such blood–borne infections as hepatitis.

Additionally, the body is not able to get rid of excess iron that accompanies each transfusion. A medication called desferoxamine is administered, usually five nights per week over a period of several hours, using an automatic pump that can be used during sleep

WWW.BOOKBAZ.IR

or taken anywhere the person goes. This medication is able to bind to the excess iron, which can then be eliminated through urine. If desferoxamine is not used regularly or is unavailable, iron overload can develop and cause tissue damage and organ damage and failure. The heart, liver, and endocrine organs are particularly vulnerable. Desferoxamine itself may rarely produce allergic or toxic side effects, including hearing damage. Signs of desferoxamine toxicity are screened for and generally develop in individuals who overuse the medication when body iron levels are sufficiently low. Overall, however, transfusion and desferoxamine therapy have increased the life expectancy of individuals with the most severe types of beta thalassemia major to the fourth or fifth decade. This can be expected to improve with time and increased developments in treatment, as well as for those with more mild forms of the disease.

New treatments offer additional options for some individuals with beta thalassemia major. Various medications can help increase production of red blood cells (i.e., erythropoeitin) or fetal hemoglobin (i.e., hydroxyurea and butyrate). Their effectiveness in ameliorating the severity of beta thalassemia is currently being investigated. The only effective cure for thalassemia is hematopoietic **stem cell transplantation** (HSCT). The blood–forming cells in the bone marrow are killed using **chemotherapy** drugs. Next, undifferentiated stem cells collected from appropriate newborn umbilical cord blood are injected into the individual with thalassemia. When the procedure is successful, these cells settle into the recipient's bone marrow and begin producing red blood cells with normal hemoglobin. When recipients and donors are carefully selected, as many as 90% of recipients are cured; however, not all individuals with thalassemia are good candidates for this procedure and there is always the risk of serious complications. Other possible treatments under investigation include **gene therapy** techniques aimed at increasing the amount of normal hemoglobin the body is able to make.

Hemoglobin H disease

Hemoglobin H disease is a relatively mild form of thalassemia that may go unrecognized. It is not generally considered a condition that will reduce one's life expectancy. Education is an important part of managing the health of an individual with hemoglobin H disease. It is important to be able to recognize the signs of severe anemia that require medical attention. It is also important to be aware of the medications, chemicals, and other exposures to avoid due to the theoretical risk they pose of causing a severe anemia event. When severe anemia occurs, it is treated with blood transfusion therapy. For individuals with hemoglobin H disease, this is rarely required. For those with the hemoglobin H/Constant Spring form of the disease, the need for transfusions may be intermittent or ongoing, perhaps on a monthly basis and requiring desferoxamine treatment. Individuals with this more severe form of the disease may also have an increased chance of requiring removal of an enlarged and/or overactive spleen.

Alpha thalassemia major

Because alpha thalassemia major is most often a condition that is fatal in the prenatal or newborn period, treatment has previously been focused on identifying affected pregnancies in order to provide appropriate management to reduce potential maternal complications. Pregnancy termination provides one form of management. Increased prenatal surveillance and early treatment of maternal complications is an approach that is appropriate for mothers who wish to continue their pregnancy with the knowledge that the baby will most likely not survive. Only a handful of infants with this condition have survived long term. Most of these infants received experimental treatment including transfusions before birth. For those infants that survive to delivery, there seems to be an increased risk of developmental problems and physical effects, particularly heart and genital malformations. Otherwise, their medical outlook is similar to a child with beta thalassemia major, with the important exception that ongoing, lifelong blood transfusions begin right at birth.

Prognosis

The prognosis for individuals with the most serious types of thalassemia has improved drastically in the last several years following recent medical advances in transfusion, chemotherapy, and transplantation therapy. Advances continue and promise to improve the life expectancy and quality of life further for affected individuals.

Prevention

Thalassemia is a genetic disorder present at birth. It cannot be prevented. Couples who suspect that they are carriers of a gene for thalassemia can have genetic counseling before trying to conceive a child and can have prenatal genetic testing to give them information about whether their child will have or be a carrier for thalassemia.

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bilirubin—A yellow pigment that is the result of hemoglobin breakdown. This pigment is metabolized in the liver and excreted from the body through the bile. Bloodstream levels are normally low; however, extensive red cell destruction leads to excessive bilirubin formation and jaundice.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Desferoxamine—The primary drug used in iron chelation therapy. It aids in counteracting the life–threatening buildup of iron in the body associated with long–term blood transfusions.

Globin—One of the component protein molecules found in hemoglobin. Normal adult hemoglobin has a pair each of alpha–globin and beta–globin molecules.

Heme—The iron–containing molecule in hemoglobin that serves as the site for oxygen binding.

Hemoglobin—Protein–iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hemoglobin A—Normal adult hemoglobin that contains a heme molecule, two alpha–globin molecules, and two beta–globin molecules.

Hemoglobin electrophoresis—A laboratory test that separates molecules based on their size, shape, or electrical charge.

Hydroxyurea—A drug that has been shown to induce production of fetal hemoglobin. Fetal hemoglobin has a pair of gamma–globin molecules in place of the typical beta–globins of adult hemoglobin. Higher–than–normal levels of fetal hemoglobin can ameliorate some of the symptoms of thalassemia.

Iron overload—A side effect of frequent blood transfusions in which the body accumulates abnormally high levels of iron. Iron deposits can form in organs, particularly the heart, and cause life–threatening damage.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Red blood cell (RBC)—Hemoglobin–containing blood cells that transport oxygen from the lungs to tissues. In the tissues, red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Thallium heart scan

Definition

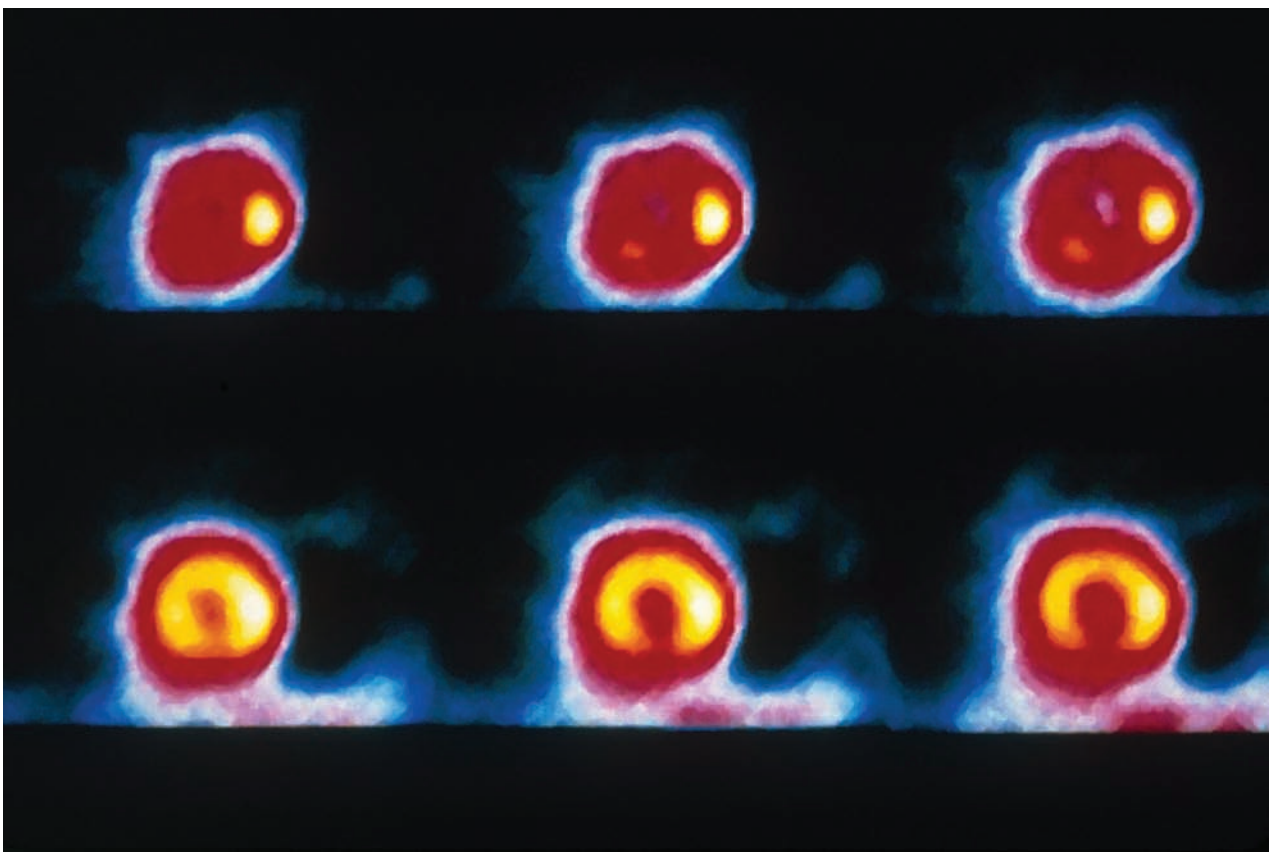
A thallium heart scan is a test using a special camera and a small amount of radioactive substance injected into the bloodstream to make an image of the blood flow to the heart.

Purpose

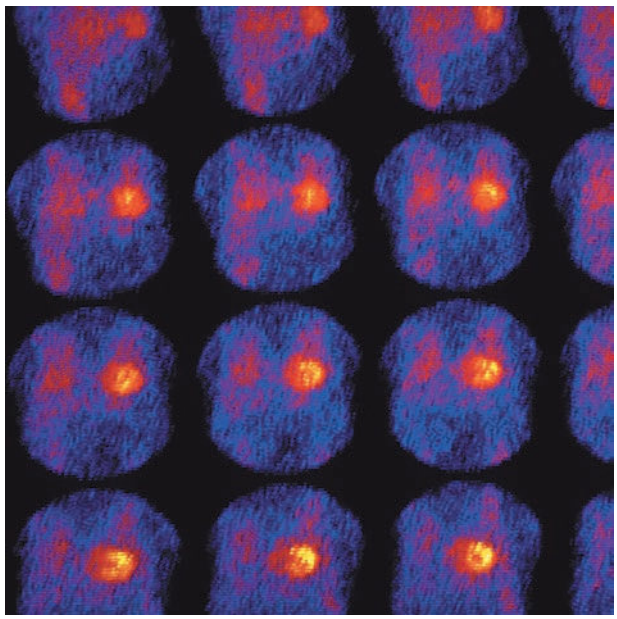
A thallium heart scan is used to evaluate the blood supply to the heart muscle. It can identify areas of the heart that may have a poor blood supply as a result of damage from a previous **heart attack** or blocked coronary arteries. While **exercise** testing has long been a standard examination in the diagnosis of **coronary artery disease**, in some cases, the thallium scan may be more sensitive and more specific in the information it provides. In other words, the test may be better able to detect a problem and to differentiate one condition from another. A thallium heart scan may more accurately detect ischemic **heart disease**. This type of scan is most likely to be helpful in cases in which the exercise test is inconclusive, the patient cannot exercise adequately, or a quantitative evaluation of blood flow is required. In addition to evaluating coronary artery disease, thallium scanning can help to evaluate blood flow following treatment of clogged arteries with **coronary artery bypass graft surgery** or **angioplasty**.

Precautions

Radioisotopes such as thallium 201 should not be administered during **pregnancy** because they may be harmful to the fetus.



Thallium heart scan showing severe coronary artery disease and poor heart perfusion. *(Scott Camazine/Science Source.)*



A thallium scan showing many images of a human heart with cold spots. *(Custom Medical Stock Photo, Inc.)*

Description

The thallium scan is performed in conjunction with an exercise **stress test**. At the end of the **stress** test (once the patient has reached the highest level of exercise he or she can comfortably achieve), a small amount of the harmless radioisotope thallium 201 is injected into the patient's bloodstream through an intravenous (IV) line. The patient then lies down under a special camera called a gamma scintillation camera, which makes photographs from the gamma rays emitted by the thallium.

The thallium attaches itself to the red blood cells and is carried throughout the body in the bloodstream. It enters the heart muscle by way of the coronary arteries and collects in the cells of the heart muscle that come into contact with the blood. Since the thallium can reach only those areas of the heart with an adequate blood supply, no thallium will show up in poorly perfused areas of the heart (perfusion defects). These areas show up as "cold spots" on the thallium scan. The patient may then be given a second injection of thallium. Several hours later, the gamma scintillation camera takes more pictures in order to get an image of the heart when the patient is at rest.

Cold spots that appear at rest as well as during exercise often indicate areas where the heart tissue has been damaged (for example, as a result of a prior heart attack). Sometimes perfusion is adequate during rest but cold spots appear during exercise, when the heart has to work harder and has a greater demand for blood. This can indicate some blockage in the coronary arteries, producing a condition called ischemia. In ischemia, the heart temporarily does not get enough blood flow. People with perfusion defects, especially perfusion defects that appear only during exercise, have the greatest risk of such future cardiac events as heart attacks.

In recent years, there have been improvements in heart scanning. Many centers now use a single photon emission computed tomographic (SPECT) camera, which provides a clearer image. Some centers also use a type of radioactive chemical called sestamibi. Sestamibi is used along with a radioactive compound called technetium. While thallium may still be better for some uses, such as providing a better image of the heart muscle itself, sestamibi may produce clearer images in overweight patients and is more useful in assessing how well the heart pumps blood.

If the patient is unable to exercise because of another medical condition, such as arthritis, he or she may be given a drug to mimic the effects of exercise on the heart. Some of these drugs include dipyridamole (Persantine), which dilates the coronary arteries; and dobutamine, which increases blood flow through the heart muscle.

Preparation

Patients should not drink alcoholic or caffeinated beverages, smoke tobacco, or ingest other nicotine products for 24 hours before the test. These substances can affect test results. Patients should also not eat anything for at least three hours before the test. They may also be instructed to stop taking certain medications during the test that may interfere with test results.

Aftercare

In some cases, another set of scans may be needed, and the patient may be given special instructions regarding eating and test preparation. Otherwise, the patient is free to return to his or her normal daily activities.

Risks

Radioisotopes such as thallium 201 should not be administered during pregnancy because they may be harmful to the fetus.

Abnormal results

Cold spots on the scan, where no thallium shows up, indicate areas of the heart that are not getting an adequate supply of blood. Thematic apperception test

Definition

The thematic apperception test (TAT) is a projective personality test that was designed at Harvard in the 1930s by Christiana D. Morgan and Henry A. Murray. Along with the MMPI and the Rorschach, the TAT is one of the most widely used **psychological tests**. A projective test is one in which a person's patterns of thought, attitudes, observational capacity, and emotional responses are evaluated on the basis of responses to ambiguous test materials. The TAT consists of 31 pictures that depict a variety of social and interpersonal situations.The subject is asked to tell a story about each picture to the examiner. Of the 31 pictures, 10 are gender-specific while 21 others can be used with adults of either sex and with children. The TAT is distributed by Harcourt Brace Educational Measurement.

Purpose

The original purpose of the TAT was to reveal the underlying dynamics of the subject's personality, such as internal conflicts, dominant drives and interests, motives, etc. The specific motives that the TAT assesses include the need for achievement, need for power, the need for intimacy, and problem-solving abilities. After World War II, the TAT was used by psychoanalysts and clinicians from other schools of thought to evaluate emotionally disturbed patients. Another shift took place in the 1970s, when the influence of the human potential movement led many psychologists to emphasize the usefulness of the TAT in assessment services—that is, using the test to help clients understand themselves better and stimulate their personal growth.

The TAT is widely used to research certain topics in psychology, such as dreams and fantasies, mate selection, the factors that motivate people's choice of occupations, and similar subjects. It is sometimes used in psychiatric evaluations to assess disordered thinking and in forensic examinations to evaluate crime suspects, even though it is not a diagnostic test. The TAT can be used to help people understand their own personality in greater depth and build on that knowledge in making important life decisions. Lastly, it is sometimes used as a screener in psychological evaluations of candidates for high-stress occupations (law enforcement, the military, religious ministry, etc.).

Precautions

The TAT has been criticized for its lack of a standardized method of administration as well as the lack of standard norms for interpretation. Studies of the interactions between examiners and test subjects have found that the race, sex, and social class of both participants influence both the stories that are told and the way the stories are interpreted by the examiner. Attempts have been made to design sets of TAT

KEY TERMS

Human potential movement—A movement in psychotherapy that began in the 1960s and emphasized maximizing the potential of each participant through such techniques as group therapy and sensitivity training.

cards for African American and for elderly test subjects, but the results have not been encouraging. In addition, the 31 standard pictures have been criticized for being too gloomy or depressing, and therefore, limiting the range of personality characteristics that the test can assess.

Description

There is no standardized procedure or set of cards for administering the TAT, except that it is a one-on-one test. It cannot be administered to groups. In one common method of administration, the examiner shows the subject only 10 of the 31 cards at each of two sessions. The sessions are not timed, but average about an hour in length.

Preparation

There is no specific preparation necessary before taking the TAT, although most examiners prefer to schedule sessions (if there is more than one) over two days.

Risks

The chief risks involved in taking the TAT are a bad "fit" between the examiner and the test subject, and misuse of the results.

Results

Since the TAT is used primarily for personality assessment rather than diagnosis of mental disorders, it does not yield a "score" in the usual sense.

Therapeutic baths

Definition

Bathing the skin in a variety of preparations in order to remove crusts, scales, and old medications or to relieve inflammation and **itching** is called a therapeutic bath.

Purpose

Baths or soaks (balneotherapy) are an easy way to treat a variety of skin disorders involving large areas of the skin. They relieve general aches and pains and can ease dry or oily, inflamed or itchy skin. Hot baths are relaxing and stimulating; cool baths can reduce inflammation.

Therapeutic baths are useful for itchy skin, **hives**, **sunburn**, chafing, **poison ivy**, **poison oak**, **eczema**, skin irritation, and dry skin. They also may help to relieve emotional tension and **stress**. Brief therapeutic baths may be useful in preventing pressure **ulcers** and other skin problems in the elderly. Colloidal oatmeal baths are sometimes recommended to reduce the itch of chicken pox.

Many family care physicians recommend warm-water therapeutic baths as a way to relieve labor pains during **childbirth** without administering drugs.

Precautions

The temperature of the water should be comfortable. The bath should not last longer than 20–30 minutes because of the tendency of these soaks to soften and wear away the skin.

A bath mat should be used, since medications may cause the floor of the tub to be slippery.

Eczema and other skin diseases can be treated with an ointment that contains a derivative of coal tar. Parts of the coal tar are volatile, so the bathroom should be well ventilated.

WWW.BOOKBAZ.IR

KEY TERMS

Eczema—An inflammation of the skin that usually itches and sometimes forms scales or blisters.

Emollient—A paste or compound having a soothing effect when applied to the skin.

Description

The tub should be filled half–full with water at a comfortable temperature. The water should not be allowed to cool too much. If an emollient action is needed, the patient should apply a lubricating agent to the skin after the bath, since this increases hydration.

Different types of therapeutic baths are used for different conditions:

- colloidal oatmeal (oatmeal that has been ground into a fine powder, e.g., Aveeno) coats, soothes, stops itch and does not dry out the skin
- potassium permanganate—a dark purple salt—makes a good disinfectant
- bath oils are used as an emollient to ease itchy skin and eczema
- cornstarch is a soothing, drying bath for itchy skin
- sodium bicarbonate can be cooling for hot, dry skin conditions
- saline (salt) water baths are used to treat lesions scattered over the body

Preparation

Keep the room warm to minimize temperature fluctuations. This precaution is particularly important when bathing elderly patients.

Aftercare

After the bath, the skin should be blotted (not rubbed) carefully with a towel. The patient should wear loose, light clothing after the bath.

Risks

A bath that is too hot can have negative consequences to the bathing individual including **burns**, skin irritation, and **dehydration**. It is key to ensure that the bath is warm but not hot. Bathing for more than 20–30 minutes can worsen some skin conditions. It is important to insure that the bathtub is cleaned thoroughly between uses, especially if the individual has any open cuts or lesions. This helps reduce the risk of infection.

Research and general acceptance

Therapeutic baths are generally considered a good way of helping to relieve the symptoms of various skin diseases and conditions. In many cases the therapeutic bath can reduce symptoms but does not treat the underlying problem. Therefore, it is important to see a doctor promptly for treatment of any underlying diseases or conditions causing the skin problems.

Training and certification

No special training or certification is generally required to take or give therapeutic baths. Some nursing and other programs may provide training in how best to assist elderly or disabled individuals in and out of the bathtub safely.

Therapeutic drug monitoring *see* **Drug therapy monitoring**

Therapeutic hypothermia

Definition

Therapeutic **hypothermia** describes the use of cold temperatures to treat medical conditions, especially cardiac arrest. The use of cold is employed to reduce the patient's body temperature as a means of decreasing tissue damage stemming from blood restriction (ischemia) due to the medical condition. Medical conditions that cause ischemia include cardiac arrest, **stroke**, **traumatic brain injury**, and birth asphyxia (dangerous oxygen deprivation in newborns). Therapeutic hypothermia has been employed for all of these conditions, but one of the most widespread uses is for cardiac arrest, particularly when the patient has cardiac arrest outside of a hospital. For instance, emergency personnel on an ambulance will chill a heart-attack patient as a means of providing immediate care while en route to a hospital. Another widespread usage is for certain surgeries, including cardiac bypass surgery. Studies are under way to verify the benefits and the fully assess the risks of therapeutic hypothermia for a variety of applications, including birth asphyxia.

Description

Therapeutic hypothermia is also known as protective hypothermia, because the lowering of a patient's body temperature by just a few degrees is thought to protect the individual from tissue damage that can result from ischemia, which is a restriction of blood supply to tissues. Tissues that do not receive sufficient blood supply will die. The idea behind therapeutic hypothermia is primarily to reduce the brain's need for oxygen and nutrients. Cold slows metabolism, and when that happens, cells need less oxygen and nutrients. In addition, once the ischemia ceases and blood flow returns to normal, that abrupt rush of blood can actually cause damage, because it can trigger inflammatory reactions that can themselves destroy cells. For that reason, patients who receive therapeutic hypothermia are warmed slowly to prevent that sudden rush.

Normal body temperature is 98.6°F (37° C). Generally therapeutic hypothermia lowers the body temperature to 90–93°F (32–33°C). This can be accomplished through a variety of methods. Some of the common methods (which may be used in combination) include:

- ice packs
- cooling blankets (either cold, air-forced blankets, or circulating cold-water blankets)
- intravenous infusion with chilled saline
- cooling helmets
- chilled enemas

Studies have shown that therapeutic hypothermia improves outcomes for patient's recovering from ischemia-related health conditions. Hypothermia is often employed during certain surgeries, including some open-heart surgeries, and as a way of preserving organs for transplant. Since 2002, its use has extended to emergency care. Two randomized clinical trials demonstrated improved survival among patients who had experienced an out-of-hospital cardiac arrest due to **ventricular fibrillation** (VF), and since those studies, therapeutic hypothermia has become the standard of care for this usage.

Although therapeutic hypothermia is now routinely administered to patients with VF cardiac arrest, many questions remain about its use overall. These range from optimal temperatures to be utilized, and the rates of cooling to lower a patient's body temperature or to rewarm a patient as they relate to therapy targeted to various conditions. Studies are continuing to provide new understanding about the best methods of therapeutic hypothermia for different conditions and for specific patients. New tools are in the works to assist with the administration of therapeutic hypothermia and the monitoring of patients undergoing the therapy. Many studies suggest a rapid cooling of patients, but current technologies do not necessarily lower body temperature as quickly as recommended. In addition, it is also difficult to accurately measure body temperature with current technology. Instead, medical professionals infer body temperature from measurements taken in such locations as the ear or the rectum.

An example of a new technology is a chemical cold pack developed by Novocor Medical Systems of Research Triangle, North Carolina. It addresses the need to deliver immediate intravenous cold saline in an ambulance. Emergency medical technicians use the

saline to to slow metabolism and reduce tissue damage in cardiac-arrest patients, but while some ambulances have refrigeration units on board to keep a cold supply at the ready, many do not. Novocor' chemical cold packs require no refrigeration, are small, and are easily stowable on ambulances. Once activated, the cold packs allow saline to be chilled as it is being delivered intravenously.

Origins

The use of therapeutic hypothermia dates at least back to the days of the Greek physician Hippocrates (c. 460–370 BCE), who advocated that wounded soldiers be packed in snow and ice. The clinical use of therapeutic hypothermia traces back to at least 1803, when the Russian method of covering patients in snow and ice was documented. At around the same time, French military surgeon Baron Dominque-Jean Larrey (1766–1842), who is often described as the founder of modern surgery in part for his development of the triage system, made important contributions to the use of therapeutic hypothermia. He observed that wounded infantrymen who were kept farther from a warming fire actually fared better than injured officers who were kept nearer. He also noted that low temperatures and ice application could prevent **shock** in patients, and recommended the use of ice and snow to reduce blood flow and facilitate amputations. He also advocated a slow rewarming of patients following the cold treatment. He wrote of tissues, or "parts": "The parts may remain for a longer or shorter period of asphyxia without losing their life; and if the cold be removed by degrees, or if the person affected by it pass gradually into a more elevated temperature, the equilibrium may be easily reestablished with the function of the organs."

In 1937, neurosurgeon Temple Fay (1895–1963) used cooling to try to help a cancer patient. He reduced the patient's body temperature to 89.6°F (33°C) for 24 hours with a goal of preventing cancer cells from multiplying (later studies showed that it was

actually higher temperatures that could damage and kill cancer cells). In the 1950s, animal studies noted that therapeutic hypothermia had benefits for the brain and heart during cardiac surgery and by 1959, neurosurgeons were inducing hypothermia for head and spinal cord injuries, and for cardiac surgeries.

The use of therapeutic hypothermia in the clinic stalled in the 1960s. This occurred because of complications stemming from the therapy. One was ventricular fibrillation, a serious heart-rhythm disturbance that leads to cardiac arrest. (This was noted particularly when the body temperature fell below 86°F [30°C].) Nonetheless, some researchers continued to study therapeutic hypothermia, and after positive results were repeatedly reported, the American Heart Association in 2002, and the European Resuscitation Council a year later, both recommended therapeutic hypothermia as a treatment for patients who experienced a cardiac arrest outside of the hospital and were comatose. In 2005, the American Heart Association produced guidelines for its use, including cooling to 89.6–93.2°F (32–34°C) for 12–24 hours in those adult patients who have an out-of-hospital cardiac arrest following VF and a return of spontaneous circulation, and potentially for those patients with an out-of-hospital non-VF arrest, and for those patients with an in-hospital arrest.

In addition, the use of therapeutic hypothermia is becoming more common in the management of acute brain injury following stroke and traumatic brain injury, due to studies indicating its neuroprotective benefits. Some medical professionals, however, are waiting to implement its usage as a measure of care until major, large-scale studies have proven its efficacy. The use of therapeutic hypothermia for neonatal hypoxic ischaemic **encephalopathy** or other birth asphyxias is also undergoing research to provide more insight into its benefits vs. risks.

Purpose

The purpose of cooling the body is to reduce the risk of ischemic injury, which results when blood supply to tissues is reduced for a period of time. When blood supply is reduced, available oxygen and glucose also drop, and when a shortage occurs, tissues can begin to die. In the case of a severe shortage, tissues can die within a matter of minutes. When the body temperature is lowered, however, metabolism slows, reducing tissue demands. Therapeutic hypothermia protects the tissues by decreasing their demand for oxygen and glucose during that period when the blood supply is low.

KEY TERMS

Birth asphyxia—Dangerous oxygen deprivation in newborns.

Ischemia—A restriction of blood supply to tissues that can cause cell death.

Shock—A life-threatening condition arising when bloodflow is decreased.

Traumatic brain injury—An injury sustained from a violent blow or jolt to the head, or sometimes to the body.

Preparation

Cooling devices or ice must be readily available for the use of therapeutic hypothermia following an out-of-hospital cardiac arrest, because treatment should begin as soon as possible.

Aftercare

Following the use of therapeutic hypothermia for cardiac arrest, warming generally is performed slowly, at approximately 0.5°F (0.3°C) per hour, until the patient's reaches 96.8°F (36°C). During and after treatment, the medical professionals will perform lab tests to monitor glucose, potassium, and blood gas levels and, if necessary, take additional measures, such as infusing insulin to counter high glucose levels.

Risks

Risks of using therapeutic hypothermia for cardiac arrest may be higher in those patients who have undergone a major surgery within the past two weeks due to the potential for infection and bleeding; patients with systemic infection/sepsis, who have a slightly elevated risk of infection; patients who are comatose due to reasons other than cardiac arrest (such as intoxication); patients who have other bleeding-related conditions.

There is a risk of overcooling a patient when using therapeutic hypothermia for cardiac arrest, so caregivers should monitor body temperature during application of this treatment to ensure that the patient's body temperature does not drop too low. In addition, for those patients receiving cooling via ice or cooling blankets, the skin should also be monitored periodically to prevent injury.

WWW.BOOKBAZ.IR

Risks associated with therapeutic hypothermia include a lowered cardiac output (the amount of blood pumped by the heart) and slowed heart rate; a longer time required for coagulation; and shivering. Afterward, patients may experience suppression of the immune system that may make them more susceptible to infection, especially pulmonary infection. Any drugs they are taking may also require a longer time to metabolize, which has the potential of affecting their health. In addition, some patients overheat while they are being rewarmed, so their temperature needs to be carefully monitored during both cooling and rewarming.

Therapeutic touch

Definition

Therapeutic touch, or TT, is a noninvasive method of healing that was derived from an ancient laying–on of hands technique. In TT, the practitioner alters the patient's energy field through an energy transfer that moves from the hands of the practitioner to the patient.

Origins

Therapeutic touch was developed in 1972 by Dora Kunz, a psychic healer, and Dolores Krieger, PhD, RN, a nurse and professor of nursing at New York University. The year before, in 1971, when Krieger was working as a registered nurse in a hospital, she became very frustrated when one of her patients, a 30-year-old female, lay dying from a gallbladder condition. In desperation, she tried what she was learning from Kunz. Within one treatment, the patient's condition began to shift and she lived, surprising the other hospital staff. Krieger and Kunz met during the study

of Oskar Estebany, a world–renowned healer. They had invited Estebany to form a study for three years, observing his work with patients. In this study, Estebany practiced laying–on of hands healing on various patients. Using her psychic and intuitive abilities, Kunz would observe and assist in the healing, while Krieger recorded the activities of the healing session and created profiles of the patients.

As the study progressed, Kunz began teaching Krieger how to heal, based on her perceptions of Estebany's healing techniques. During her research of ancient healing methods, Krieger concluded that the energy transfer between the healer and the healee that takes place in a TT session is *prana*, an Eastern Indian concept representing energy, vitality, and vigor. Krieger then combined her research with Kunz's techniques to create TT.

TT was initially developed for persons in the health professions, but is currently taught worldwide to anyone who is interested in learning the technique. An estimated 100,000 people around the world have been trained in TT; 43,000 of those persons are healthcare professionals, many of whom use TT in conjunction with traditional medicine, as well as osteopathic, **chiropractic**, naturopathic, and homeopathic therapies. TT is taught in over 100 colleges, universities, and medical schools.

Benefits

The major effects of TT are relaxation, **pain** reduction, accelerated healing, and alleviation of psychosomatic symptoms. Studies have shown that TT has a beneficial effect on the blood as it has the ability to raise hemoglobin values. It also affects brain waves to induce a relaxed state. TT can induce the relaxation response often within five minutes.

Krieger has said that it is not individual illnesses that validate the effectiveness of TT, but rather, it is questioned which systems are most sensitive to TT. She and others have found that the most sensitive is the autonomic nervous system (ANS), which, for example, controls urination. The ANS is followed by dysfunctions of lymphatic and circulatory systems, and then finally musculoskeletal systems. In addition, the female endocrine system is more sensitive to TT than the corresponding male system. Thus, TT helps with **dysmenorrhea**, **amenorrhea**, problems with **contraception**, and the course of **pregnancy**.

TT is reported to have a positive effect on the immune system and accelerates the healing of **wounds**. Nurses use therapeutic touch in operating rooms to relax patients before surgery and in recovery rooms on postoperative patients to help speed the healing process. TT is used in the treatment of terminally ill patients, such as those with cancer and autoimmune deficiency syndrome (**AIDS**), to relieve **anxiety** and **stress**, create peace of mind, and reduce pain.

Many nurses use TT in the nursery. The conditions of many premature babies who received TT reportedly improved rapidly. TT has been used to calm colicky infants, assist women in **childbirth**, and increase milk let-down in breast-feeding mothers.

Other claims of TT include relief of acute pain, nausea, **diarrhea**, tension and migraine headaches, **fever**, and joint and tissue swelling. TT has been used to treat thyroid imbalances, **ulcers**, psychosomatic illnesses, **premenstrual syndrome**, Alzheimer's disease, **stroke** and **coma**, **multiple sclerosis**, **measles**, infections, **asthma**, and bone and muscle injuries.

Therapeutic touch is performed in many different locations, including healing centers, delivery rooms, hospitals, hospice settings, accident scenes, homes, and schools.

Description

Therapeutic touch treats the whole person: relaxes the mind, heals the body, and soothes the spirit. The principle behind it is that it does not stop at the skin. The human body extends an energy field, or aura, several inches to several feet from the body. When illness occurs, it creates a disturbance or blockage in the vital energy field. The TT practitioner uses her/his hands to sense the blockage or disturbance. In a series of gentle strokes, the healer removes the disturbance and rebalances the energy to restore health.

The TT session generally lasts about 20–30 minutes. Although the name is therapeutic touch, there is generally no touching of the physical body, only the energetic body or field. It is usually performed on fully clothed patients who are either lying down on a flat surface or sitting up in a chair.

Each session consists of five steps. Before the session begins, the practitioner enters a state of quiet **meditation** in which he/she becomes centered and grounded in order to establish intent for the healing session and to garner the compassion necessary to heal.

The second step involves the assessment of the person's vital energy field. During this step, the practitioner places the palms of his/her hands 2–3 in (5–8 cm) from the patient's body and sweeps them over the energy field in slow, gentle strokes beginning at the head and moving toward the feet. The practitioner might feel heat, coolness, heaviness, pressure, or a prickly or tingling

sensation. These cues, as they are called, each signal a blockage or disturbance in the field.

To remove these blockages and restore balance to the body, the practitioner then performs a series of downward sweeping movements to clear away any energy congestion and smooth the energy field. This is known as the unruffling process and is generally performed from head to feet. To prevent any energy from clinging to him/her, the practitioner shakes his/her hands after each stroke.

During the next phase, the practitioner acts as a conduit to transfer energy to the patient. The energy used is not solely the energy of the practitioner. The practitioner relies on a universal source of energy so as not to deplete his/her own supply. In short, the healer acts as an energy support system until the patient's immune system is able to take over.

The practitioner then smoothes the field to balance the energy and create a symmetrical flow. When the session is over, it is recommended that the patient relax for 10–15 minutes in order for the energies to stabilize.

Side effects

The side effects reported occur when an excess of energy enters the body for an extended period of time creating restlessness, irritability, and hostility, or increasing anxiety and pain. **Burns** are sensitive to therapeutic touch, and it is recommended that TT be performed on burned tissue for short periods, generally two to three minutes at a time.

Research and general acceptance

Therapeutic touch is not generally accepted by Western medical professionals. Basic and anecdotal research has been performed on TT since its development in 1972, although little quantitative research has been carried out. It is based on a theory derived from formal research. It began as the basis of Dolores Krieger's postdoctoral research.

Dolores Krieger has performed extensive research on TT, including with pregnant women, and has noted that the following changes occur in a patient after short, consistent treatment: relaxation within the first five minutes of a session, a reduction of pain, and the acceleration of the healing process.

One study was created to determine the effect TT would have on wounds that resulted from a biopsy of the upper arm. Forty-four patients placed their injured arms through a hole in a door. Twenty-two of them received TT on their arms. The other half received no treatment. The wounds treated with TT healed more quickly than the wounds that received no treatment.

In 1998, a study was performed on 27 patients with **osteoarthritis** in at least one knee. For six weeks, the patients were treated with therapeutic touch, mock therapeutic touch, or standard care. According to *The Journal of Family Practice*, the journal that published the study, the results showed that the group who had received TT had "significantly decreased pain and improved function as compared with both the placebo and control groups."

Therapeutic touch can be combined with a number of different therapies, including **acupressure**, massage, mental imagery, **physical therapy**, and **yoga**. When combined with massage and physiotherapy, TT may reduce tension headaches, back pain, stress-related problems, circulatory problems, and **constipation**. **Shiatsu** and TT may help **sinusitis**, digestive disorders, **muscle cramps**, menstrual difficulties, and **insomnia**. Yoga and TT may be beneficial in the treatment of **bronchitis**, asthma, blood pressure, **fatigue**, and anxiety.

TT is practiced in over 70 countries worldwide: by Egyptians and Israelis during fighting in the Gaza Strip; in South Africa to reduce racial strife; and in Poland, Thailand, and the former Soviet Union.

Training and certification

Therapeutic touch is taught at over 100 universities and nursing and medical schools around the United States and Canada. Although it was developed primarily for nurses, anyone can learn TT.

State laws vary regarding the practice of TT. In general, laypersons are allowed to practice TT within their families. Therapeutic touch is considered an extension of healthcare skills, so most healthcare professionals are covered under the state medical practice act.

Many hospitals have established policies allowing nurses and staff to perform TT on patients at no extra charge. The American Nurse's Association often holds workshops on TT at national conventions. Therapeutic touch classes are often held for the general public through community education, healing clinics, and holistic schools.

Third-spacing

Definition

Third-spacing is a condition in which the normal distribution of fluid (water) in the body is disturbed; specifically, fluid moves out of the blood plasma in the circulatory system into a so-called third space or compartment where it does not normally collect, and where it is unavailable to maintain adequate plasma volume in the bloodstream. Third-spacing is not a disorder in its own right but a consequence of such other disorders such as burns, pancreatitis, peritonitis, cancer, blood loss, anaphylaxis, hemorrhagic fevers, and various liver diseases. Third-spacing withdraws fluid from the other body compartments and leads to hypovolemia, a state of decreased blood volume (more specifically, a decrease in the volume of blood plasma) that may lead to shock, respiratory distress, and loss of kidney function.

To understand why the term "third space" is used, it is helpful to define the first and second spaces, or fluid compartments. The first space is usually defined as the intracellular space (compartment); that is, the fluid contained within the cells of the body. The second space is defined as the extracellular space (compartment). The extracellular compartment is subdivided into the intravascular compartment (the space within the blood vessels), which contains blood plasma; the transcellular compartment, which includes digestive juices, lymph, and cerebrospinal fluid; and the interstitial compartment (also called the tissue space), which contains fluid that surrounds cells but does not circulate in the way that blood plasma does. The interstitial compartment is the so-called third space; when this third space fills with fluid withdrawn from blood plasma, the tissues swell, resulting in edema or such severe forms of third-spacing as abdominal ascites, tissue death, or pleural effusions.

Description

Under normal conditions, the body maintains a balance, or homeostasis, of the location and movement of fluid in the body. About 60–65% of body water is contained as intracellular fluid (ICF), and the remaining 35–40% as extracellular fluid (ECF). The average adult contains about 40 qt. of water in total, about 25 qt. of it as ICF. The intravascular compartment of the ECF holds about 3.5 qt. of blood plasma; the transcellular compartment contains 1 or 2 qt. of fluid; and the interstitial compartment holds about 11 or 12 qt. of fluid. Fluid is constantly moving from one body compartment to another in order to maintain blood pressure, supply cells and organs with oxygen and nutrients, remove wastes from the body, regulate body temperature, and maintain other vital processes.

In general, body fluid moves from the intravascular space to the extravascular, and from the intracellular space to the extracellular. The movement of fluid from the intravascular to the extravascular space occurs primarily by diffusion, which is a form of passive transport. In diffusion, molecules move across a membrane from an area of higher concentration of a solute to an area of lower concentration. Diffusion in blood vessels is controlled by two forces, hydrostatic pressure and oncotic pressure. Hydrostatic pressure refers to the pressure of the blood plasma against the wall of the blood vessel. If the blood vessel is strong (as in the case of arteries), the fluid will remain within the intravascular space. But if the vessel is weak (as occurs when capillaries are damaged), hydrostatic pressure will push fluid through the capillary wall and into the interstitial space. The capillaries may be weakened by traumatic injury or by surgery, which often damages the endothelial cells that line them; or by burns, which often lead to the pooling of tissue fluid in the burn site.

Oncotic pressure refers to the pressure exerted by proteins in blood plasma—particularly albumin—that act to retain fluid within the blood plasma. If the level of serum albumin is too low (hypoalbuminemia), as may happen in liver disease, kidney disease, or chronic malnutrition, oncotic pressure drops, allowing fluid to leak from the intravascular compartment through the capillaries into the interstitial space and cause edema. If the fluid from the intravascular compartment moves into and collects in the spaces between the tissues and organs in the abdomen, it can cause ascites. If the fluid moves into the alveoli and the interstitial spaces in the lungs, it can cause pulmonary edema; if it moves into the pleural cavity (the space between the membranes that cover the lungs and line the chest wall), it can lead to pleural effusion.

In addition to fluid loss from the intravascular compartment resulting from destruction or weakening of the capillaries or from hypoalbuminemia, third-spacing may also result from the removal of lymph nodes during cancer surgery. When the lymph nodes are removed, a portion of the lymphatic system is blocked. Plasma proteins and fluid cannot be

WWW.BOOKBAZ.IR

reabsorbed into the general circulation and accumulate in the tissues in the area where the lymph nodes were removed. Postmastectomy lymphedema is a common example of this process.

Third-spacing is a process with two phases, loss and reabsorption. During the loss phase, weakening or increased permeability of the capillaries leads to the movement of fluid and proteins from the intravascular compartment to the interstitial space. This phase lasts 24–72 hours after the trauma or inflammatory process (burns, surgery, sepsis, traumatic injury) that caused the capillaries to become increasingly permeable. During the reabsorption phase, tissues begin to heal and fluid is reabsorbed from the interstitial space back into the intravascular space. Such signs of third-spacing as weight gain, hypovolemia, and low urinary output begin to return to normal.

Risk factors

Risk factors for third-spacing include:

- recent traumatic injury or major surgery, particularly abdominal surgery
- recent severe burns
- recent exposure to dengue or other hemorrhagic fevers
- history of liver disease
- history of heart failure
- recent bacterial or viral infection
- sepsis syndrome
- history of heavy drinking and/or poor nutrition
- long-term use of diuretics
- history of severe allergic reactions to insect venom, certain foods, or certain medications

Demographics

Third-spacing appears to be equally common in both sexes and in all races and ethnic groups. It is more likely to occur in adults than in children because a number of disorders and diseases that may lead to third-spacing are more common in adults.

Causes and symptoms

Causes

Third-spacing may result from a number of possible causes:

- Hypovolemia. Low blood plasma volume may in turn be caused by blood loss from trauma or hemorrhage; or dehydration resulting from heavy sweating, nausea, vomiting, or diarrhea.
- Hypoalbuminemia. Abnormally low levels of albumin in blood plasma may result from malnutrition (insufficient protein intake), severe burns, inadequate iron intake, liver disease, or liver dysfunction (albumin is synthesized in the liver). Other causes of hypoalbuminemia include malabsorption of nutrients; hypothyroidism; cancer; alcoholism; and kidney disease.
- Increased permeability of the capillaries in the circulatory system. This condition may result from localized burns or trauma, or from systemic disorders like anaphylaxis or disseminated intravascular coagulation.
- Hyponatremia. An abnormally low level of sodium in the blood may result from vomiting or diarrhea; overuse of diuretic medications; or plasma volume overload resulting from heart failure, kidney disease, cirrhosis of the liver, or hypothyroidism.
- Blockage of the lymphatic system. Surgical removal of cancerous lymph nodes is the most common cause of this condition.
- Increased fluid volume in the intravascular compartment. Fluid overload may result from kidney dysfunction or from health professionals administering too large a quantity of replacement fluid.

Symptoms

The symptoms of third-spacing include the following:

- weakness and fatigue
- decreased output of urine
- tachycardia (rapid heartbeat)
- weak pulse
- lowered temperature
- increased rate of respiration
- increased thirst
- weight gain
- (in some cases) confusion and altered mental status

Diagnosis

In many cases, the underlying cause of the patient's third-spacing will be obvious, either from the patient's recent admission to the hospital for major surgery or emergency treatment of traumatic injury, burns, or an episode of anaphylaxis; or from the patient's history of such disorders as hepatitis, kidney disease, alcoholism, or thyroid disorders. In cases in which the cause of third-spacing is less obvious, the diagnostic workup will typically include the following tests or measurements:

KEY TERMS

Albumin—A protein synthesized in the liver that makes up about 60% of the protein content of blood plasma. Albumin is necessary to maintain oncotic pressure within the circulatory system.

Anaphylaxis—A severe allergic reaction that is rapid in onset, affects many body systems, and is potentially fatal. Respiratory distress, a sudden drop in blood pressure, and hives or a skin rash.

Ascites—An abnormal accumulation of fluid in the peritoneal cavity, which is the space between the two membranes that separate the organs in the abdominal cavity from the abdominal wall.

Diffusion—Passive movement of molecules across a membrane from an area of higher concentration to an area of lower concentration.

First space—The intracellular fluid in the body (ICF).

Hypoalbuminemia—An abnormally low level of albumin in the blood plasma.

Hypovolemia—A decrease in the volume of blood plasma.

Oncotic pressure—A form of osmotic pressure exerted by proteins (usually albumin) in blood plasma that tend to draw fluid into the circulatory system. It is also called colloid osmotic pressure.

Osmosis—The movement of water (or another solvent) across a semipermeable membrane from an area of lower concentration of a solute toward an area of higher concentration.

Pleural effusion—An excessive accumulation of fluid in the space between the lungs and the chest wall. A pleural effusion can impair breathing due to the pressure of the fluid on the lungs.

Second space—The extracellular fluid in the body (ECF).

Solute—Any substance that is dissolved in another substance, which is called a solvent.

Third space—The interstitial space.

- A complete blood count, which may provide clues to the presence of an infection
- A complete metabolic panel, which will indicate the levels of sodium and albumin in the blood plasma as well as assess the patient's kidney and liver function
- Hemoglobin and hematocrit measurements; high values suggest hypovolemia, low values may indicate fluid overload
- An echocardiogram to measure the patient's heart function and volume status
- Ongoing measurement of the patient's weight and urine output
- Patients who may have developed a bowel perforation may be given a CT scan to determine whether surgery may be necessary.It is, however, difficult to quantify the actual amount of fluid in an individual patient's third space.

Treatment

Treatment of third-spacing is based on treatment of the underlying condition. Giving more fluids to correct the protein and electrolyte imbalances in the blood is only a short-term measure performed during the loss phase of third-spacing in order to reverse the patient's hypovolemia and low blood pressure. Fluid infusion is done to prevent shock and kidney failure during the loss phase. When the reabsorption phase begins, treatment is focused on preventing circulatory overload and high blood pressure, which can lead to pulmonary edema.

In cases where prolonged third-spacing has led to loss of adequate blood supply to the intestines, the surgeon may need to reopen the patient's abdomen to remove a perforated bowel or to allow the edema to subside.

Prognosis

The prognosis of third-spacing depends on the patient's general health and the underlying cause of the fluid shift.

Prevention

Prevention of burns and traumatic injuries will prevent some cases of third-spacing, as will avoidance of hemorrhagic fevers and such liver diseases as hepatitis and cirrhosis associated with alcoholism. Recent changes in the amount of fluids infused during surgery have lowered the rates of postoperative third-spacing in many hospitals. Third-spacing that follows cancer surgery or gastrointestinal surgery, however, is not always preventable.

Thoracentesis

Definition

Also known as pleural fluid analysis, thoracentesis is a procedure that removes fluid or air from the chest through a needle or tube.

Purpose

The lungs are lined on the outside with two thin layers of tissue called pleura. The space between these two layers is called the pleural space. Normally, there is only a small amount of lubricating fluid in this space. Liquid and/or air accumulates in this space between the lungs and the ribs from many conditions. The liquid is called a **pleural effusion**; the air is called a pneumothorax. Most pleural effusions are complications emanating from metastatic malignancy (movement of cancer cells from one part of the body to another). Most malignant pleural effusions are detected and controlled by thoracentesis. Thoracentesis is also performed as a diagnostic measure. In these cases, only small amounts of material need to be withdrawn.

Symptoms of a pleural effusion include breathing difficulty, chest **pain**, **fever**, weight loss, **cough**, and **edema**. Removal of air is often an emergency procedure to prevent suffocation from pressure on the lungs. Negative air pressure within the chest cavity allows normal respiration. The accumulation of air or fluid within the pleural space can eliminate these normal conditions and disrupt breathing and the movement of air within the chest cavity. Fluid removal is performed to reduce the pressure in the pleural space and to analyze the liquid. In addition, thoracentesis was traditionally used to remove blood from the chest cavity. This is rare now that the placement of a thoracostomy tube has proven to be a more effective and safer method.

Thoracentesis often provides immediate abatement of symptoms. However, fluid often begins to reaccumulate. A majority of patients will ultimately require additional therapy beyond a simple thoracentesis.

There are two types of liquid in the pleural space, one having more protein in it than the other. More watery liquids are called transudates; thicker fluids are called exudates. On the basis of this difference, the cause of the effusion can more easily be determined.

Transudates

Thin, watery fluid oozes into the chest either because back pressure from circulation squeezes it out or because the blood has lost some of its osmotic pressure.

- Heart failure creates back pressure in the veins as blood must wait to be pumped through the heart.
- A pulmonary embolism is a blood clot in the lung. It will create back pressure in the blood flow and also damage a part of the lung so that it leaks fluid.

- Cirrhosis is a sick, scarred liver that both fails to make enough protein for the blood and also restricts the flow of blood through it.
- Nephrosis is a collection of kidney disorders that change the osmotic pressure of blood and allow liquid to seep into body cavities.
- Myxedema is a disease caused by too little thyroid hormone.

Exudates

Thicker, more viscous fluid is usually due to greater damage to tissues, allowing blood proteins as well as water to seep out.

- Pneumonia, caused by viruses and by bacteria, damages lung tissue and can open the way for exudates to enter the pleural space.
- Tuberculosis can infect the pleura as well as the lungs and cause them to leak liquid.
- Cancers of many types settle in the lungs or the pleura and leak liquids from their surface.
- Depending upon its size and the amount of damage it has done, a pulmonary embolism can also produce an exudate.
- Several drugs can damage the lung linings as an unexpected side effect. None of these drugs is commonly used.
- An esophagus perforated by cancer, trauma, or other conditions can spill liquids and even food into the chest. The irritation creates an exudate in the pleural space.
- Pancreatic disease can cause massive fluid in the abdomen, which can then find its way into the chest.
- Pericarditis is an inflammation of the sac that contains the heart. It can ooze fluid from both sides—into the heart's space and into the chest.
- Radiation to treat cancer or from accidents with radioactive materials can damage the pleura and lead to exudates.
- A wide variety of autoimmune diseases attack the pleura. Among these are rheumatoid arthritis and systemic lupus erythematosus (SLE).
- Many other rare conditions can also lead to exudates.

Blood

Blood in the chest (hemothorax) is infrequently seen outside of two conditions:

- major trauma can sever blood vessels in the chest, causing them to bleed into the pleural space
- cancers can ooze blood as well as fluid; they do not usually bleed massively

Chyle

Occasionally, the liquid that comes out of the chest is neither transparent nor bloody, but milky. This is due to a tear of the large lymphatic channel—the thoracic duct carrying lymph fluid from the intestines to the heart. It is milky because it is transporting fats absorbed in the process of digestion. The major causes of chylothorax are:

- injury from major trauma, such as an automobile accident
- cancers eroding into the thoracic duct

Air

Air in the pleural space is called pneumothorax. Air can enter the pleural space either directly through a hole between the ribs or from a hole in the lungs. Holes in the lungs are sometimes spontaneous, sometimes traumatic, and sometimes the result of disease opening a communication to the air in the lung.

Precautions

Care must be taken not to puncture the lung when inserting the needle. Thoracentesis should never be performed by inserting the needle through an area with an infection. An alternative site needs to be found in these cases. Patients who are on **anticoagulant drugs** should be carefully considered for the procedure.

Description

The usual place to tap the chest is below the armpit (axilla). Under sterile conditions and local **anesthesia**, a needle, a through-the-needle-catheter, or an over-the-needle catheter may be used to perform the procedure. Overall, the catheter techniques may be safer. Fluid or air is withdrawn. Fluid is sent to the laboratory for analysis. If the air or fluid continue to accumulate, a tube is left in place and attached to a one-way system so that it can drain without sucking air into the chest.

Preparation

The location of the fluid is pinpointed through x ray or **ultrasound**. Ultrasound is a more accurate method when the effusion is small. A sedative may be administered in some cases but is generally not recommended. Oxygen should be given to the patient.

WWW.BOOKBAZ.IR

KEY TERMS

Axilla—Armpit.

Catheter—A tube that is moved through the body for removing or injecting fluids into body cavities.

Hypovolemic shock—Shock caused by a lack of circulating blood.

Osmotic pressure—The pressure in a liquid exerted by chemicals dissolved in it. It forces a balancing of water in proportion to the amount of dissolved chemicals in two compartments separated by a semi-permeable membrane.

Pleura—Two thin layers lining the lungs on the outside.

Aftercare

As long as the tube is in the chest, the patient must lie still. After it is removed, x rays will determine if the effusion or air is reaccumulating—though some researchers and clinicians believe chest x rays do not need to be performed after routine thoracentesis.

Risks

Reaccumulation of fluid or air is a possible complications, as are hypovolemic shock (shock caused by a lack of circulating blood) and infection. Patients are at increased risk for poor outcomes if they have a recent history of anticoagulant use, have very small effusions, have significant amounts of fluid, have poor health leading into this condition, have positive airway pressure, and have **adhesions** in the pleural space. A pneumothorax can sometimes be caused by the thoracentesis procedure. The use of ultrasound to guide the procedure can reduce the risk of pneumothorax.

Thoracentesis can also result in hemothorax, or bleeding within the thorax. In addition, such internal structures as the diaphragm, spleen, or liver, can be damaged by needle insertion. Repeat thoracenteses can increase the risk of developing hypoproteinemia (a decrease in the amount of protein in the blood).

Thoracic outlet syndrome

Definition

Thoracic outlet syndromes are a group of disorders that cause **pain** and abnormal nerve sensations in the neck, shoulder, arm, and/or hand.

Description

The thoracic outlet is an area at the top of the rib cage, between the neck and the chest. Several anatomical structures pass through this area, including the esophagus, trachea, and nerves and blood vessels that lead to the arm and neck region. The area contains the first rib; collar bone (clavicle); the arteries beneath the collar bone (subclavian artery), which supply blood to the arms; a network of nerves leading to the arms (brachial plexus); and the top of the lungs.

Pain and other symptoms occur when the nerves or blood vessels in this area are compressed. The likelihood of blood vessels or nerves in the thoracic outlet being compressed increases with increased size of body tissues in this area or with decreased size of the thoracic outlet. The pain of thoracic outlet syndrome is sometimes confused with the pain of **angina** that indicates heart problems. The two conditions can be distinguished from each other because the pain of thoracic outlet syndrome does not appear or increase when walking, while the pain of angina does. Also, the pain of thoracic outlet syndrome usually increases if the affected arm is raised, which does not happen in cases of angina.

There are three types of thoracic outlet syndromes:

- True neurogenic thoracic outlet syndrome is caused by a compression of the nerves in the brachial plexus. Abnormal muscle or other tissue causes the problem.
- Arterial thoracic outlet syndrome is caused by compression of the major artery leading to the arm, usually by a rib.
- Disputed thoracic outlet syndrome describes patients who have chronic pain in the shoulders and arms and have no other disease or syndrome, but the underlying cause cannot be accurately determined.

Thoracic outlet syndrome is most common in women who are 35 to 55 years of age.

Causes and symptoms

Compression of blood vessels or nerves in the thoracic outlet causes pain and/or abnormal nerve sensations. Compression usually occurs at the location where the blood vessels and nerves pass out of the thoracic outlet into the arm.

There are several factors that contribute to a person developing thoracic outlet syndrome. Poor posture is a major cause and is easy to treat. A person's physical makeup also can cause thoracic outlet syndrome. For example, abnormalities of certain anatomical structures can put pressure on blood vessels or nerves. Typical abnormalities that can cause problems are malformed ribs and too narrow an opening between the collar bone and the first rib.

The main symptom is pain in the affected area. The patient can also develop weakness in the arm and hands, tingling nerve sensations, and a condition called Raynaud's syndrome. In Raynaud's syndrome, exposure to cold causes small arteries in the fingers to contract, cutting off blood flow. This causes the fingers to turn pale. In very severe cases of blood vessel compression, **gangrene** can result. Gangrene is the death of tissue caused by the blood supply being completely cut off.

In arterial thoracic outlet syndrome, the artery beneath the collar bone leading to the arm is compressed, causing the artery to increase in size. **Blood clots** (thrombi) may form in the blood vessel. When blood vessels are compressed, the hands, arms, and shoulders do not receive proper blood supply. They can swell and turn blue from a lack of blood.

In true neurogenic thoracic outlet syndrome, the nerves most affected are those of the network of nerves supplying the chest, shoulder, arm, forearm, and hand (brachial plexus). When a nerve is affected in thoracic outlet syndrome it produces a tingling sensation (paresthesia). It can also cause weakness in the hand and reduced sensation in the palm and fingers.

Diagnosis

There are no specific diagnostic tests for thoracic outlet syndromes. The diagnosis is made by ruling out other diseases and by observing the patient. Two nonspecific tests that can suggest the presence of thoracic outlet syndrome are the Adson test and the Allen test. In the Adson test, the patient takes a deep breath and tilts his or her head back and turns it to one side. The physician tests to see if the strength of the patient's pulse is reduced in the wrist on the arm on the opposite side of the head turn. In the Allen test, the arm in which the patient is experiencing symptoms is raised and rotated while the head is turned to the opposite side. The physician tests to see if the pulse strength at the wrist is reduced. If the strength of the pulse is reduced in either of these two tests it indicates compression of the subclavian artery.

KEY TERMS

Angina—A severe constricting pain in the chest, usually caused by a lack of oxygen to the heart.

Neurogenic—Caused by nerves; originating in the nerves.

Subclavian—Located beneath the collarbone (clavicle).

Occasionally, examination with a stethoscope may reveal abnormal sounds in affected blood vessels. X rays can reveal constrictions in blood vessels if a special dye is injected into the bloodstream to make the blood vessels visible (**angiography**).

Certain tests are available to help with the diagnosis of nerve compression. These include the nerve conduction velocity test and somatosensory evoked potential test. In the nerve conduction velocity test, electrodes are placed at various locations on the skin along a nerve that is being tested. A mild electrical impulse is delivered through an electrode at one end of the nerve and the electrical activity is recorded by the other electrodes. The time it takes for the electrical impulse to travel down the nerve from the stimulating electrodes to the recording electrodes is used to calculate the nerve conduction velocity. This can be used to determine if any nerve damage exists.

In a somatosensory evoked potential test, electrodes are placed on the skin at the scalp, neck, shoulder, and wrist. A mild electrical impulse is delivered at the wrist, and a recording is made of the response by the brain and spinal cord. This test also can determine the presence of nerve damage.

Treatment

The main treatment for thoracic outlet syndrome is **physical therapy**. Exercises aimed at improving the posture of the affected person are also useful. In some cases, surgery can be performed to remove the cervical

WWW.BOOKBAZ.IR

rib if this is causing the problem and physical therapy has failed to work. However, surgery is generally not used to treat thoracic outlet syndrome.

Prognosis

Treatment of true neurogenic and arterial thoracic outlet syndromes is usually successful. Treatment of disputed thoracic outlet syndrome is often unsuccessful. This may relate to the uncertainty of the underlying cause of the pain.

Thoracic surgery

Definition

Thoracic surgery is any surgery performed in the chest (thorax).

Purpose

The purpose of thoracic surgery is to treat diseased or injured organs in the thorax, including the esophagus (muscular tube that passes food to the stomach), trachea (windpipe that branches to form the right bronchus and the left bronchus), pleura (membranes that cover and protect the lung), mediastinum (area separating the left and right lungs), chest wall, diaphragm, heart, and lungs.

General thoracic surgery is a field that specializes in diseases of the lungs and esophagus. The field also encompasses accidents and injuries to the chest, **esophageal disorders** (**esophageal cancer** or esophagitis), lung cancer, **lung transplantation**, and surgery for **emphysema**.

Description

Thoracic surgery is performed in a hospital by a specialist in **general surgery** who has received advanced training in thoracic surgery.

The most common diseases requiring thoracic surgery include lung cancer, chest **trauma**, esophageal cancer, emphysema, and lung transplantation.

Lung cancer

Lung cancer is one of the most significant **public health** problems in the world. Approximately 228,190 new cases of lung and bronchial cancer were diagnosed in 2013. It is the second most common type of cancer, and the leading cause of cancer deaths among both men and women, killing about 160,340 people annually. The overall five-year survival rate for all types of lung cancer is about 16.3%, as compared to 65.2% for **colon cancer**, 90% for **breast cancer**, and 99.9% for **prostate cancer**.

Lung cancer develops primarily by exposure to toxic chemicals. Cigarette **smoking** is the most important risk factor responsible for the disease. Other environmental factors that may predispose a person to lung cancer include industrial substances such as arsenic, nickel, chromium, asbestos, radon, organic chemicals, air pollution, and radiation.

Most cases of lung cancer develop in the right lung because it contains the majority (55%) of lung tissue. Additionally, lung cancer occurs more frequently in the upper lobes of the lung than in the lower lobes. The tumor receives blood from the bronchial artery (a major artery in the pulmonary system).

Adenocarcinoma of the lung is the most frequent type of lung cancer, accounting for 45% of all cases. This type of cancer can spread (metastasize) earlier than another type of lung cancer called squamous cell carcinoma, which occurs in approximately 30% of lung cancer patients. Approximately 66% of squamous cell carcinoma cases are centrally located. They expand against the bronchus, causing compression. Small-cell carcinoma accounts for 20% of all lung cancers; the majority (80%) are centrally located. Small-cell carcinoma is a highly aggressive lung cancer, with early metastasis to distant sites such as the brain and bone marrow (the central portion of certain bones that produce formed elements that are part of blood).

Most lung tumors are not treated with thoracic surgery since patients seek medical care later in the disease process. **Chemotherapy** increases the rate of survival in patients with limited (not advanced) disease. Surgery may be useful for staging or diagnosis. Pulmonary resection (removal of the tumor and neighboring lymph nodes) can be curative if the tumor is less than or equal to 1.8 in. (3 cm), and presents as a solitary nodule. Lung tumors spread to other areas through neighboring lymphatic channels. Even if thoracic surgery is performed, postoperative chemotherapy may be indicated to provide comprehensive treatment (i.e., to kill any tumor cells that may have spread via the lymphatic system).

Genetic engineering has provided insights related to the growth of tumors. A genetic mutation called a k-ras mutation frequently occurs, and is implicated in 90% of genetic mutations for adenocarcinoma of the lung. Mutations in the cancer cells make them resistant to chemotherapy, necessitating the use of multiple chemotherapeutic agents.

Chest trauma

Chest trauma is a medical/surgical emergency. Initially, the chest should be examined after an airway is maintained. The mortality (death) rate for trauma patients with respiratory distress is approximately 50%. This figure rises to 75% if symptoms include both respiratory distress and **shock**. Patients with respiratory distress require endotracheal intubation (passing a plastic tube from the mouth to the windpipe) and mechanically assisted ventilator support. Invasive thoracic procedures are necessary in emergency situations.

Trauma requiring urgent thoracic surgery may include any of the following problems: a large clotted hemothorax, massive air leak, esophageal injury, valvular cardiac (heart) injury, proven damage to blood vessels in the heart, or chest wall defect.

Esophageal cancer

The number of new cases of esophageal cancer is slowly rising, with about 17,990 people diagnosed annually. While the cause of esophageal cancer is not precisely known, the greatly increased rate of esophageal cancer seems to be tied to the epidemic of **obesity** in the United States. Obesity results in acid reflux into the esophagus, chronic esophageal irritation, and progression to abnormal cell types that result in esophageal cancer, specifically of adenocarcinoma of the esophagus. Smoking and alcohol seem to also result in chronic esophageal irritation, leading to an association with squamous cell carcinoma of the esophagus.

Difficulty swallowing (dysphagia) is the cardinal symptom of esophageal cancer. Radiography, **endoscopy**, computerized axial tomography (CT scan), and ultrasonography are part of a comprehensive diagnostic

WWW.BOOKBAZ.IR

evaluation. The standard operation for patients with resectable esophageal carcinoma includes removal of the tumor from the esophagus, a portion of the stomach, and the lymph nodes (within the cancerous region).

Emphysema

Lung volume reduction surgery (LVRS) is the term used to describe surgery for patients with emphysema. LVRS is intended to help persons whose disabling dyspnea (difficulty breathing) is related to emphysema and does not respond to medical management. Breathlessness is a result of the structural and functional pulmonary and thoracic abnormalities associated with emphysema. Surgery will assist the patient, but the primary pathogenic process that caused the emphysema is permanent because lung tissues lose the capability of elastic recoil during normal breathing (inspiration and expiration).

Patients are usually transferred out of the intensive care unit (ICU) within one day of surgery. **Physical therapy** and **rehabilitation** (coughing and breathing exercises) begin soon after surgery, and the patient is discharged when deemed clinically stable.

Lung transplantation

There are various types of lung transplantations: unilateral (one lung, the most common type); bilateral (both lungs); heart-lung; and living donor lobe transplantation.

The survival rate for persons receiving a single lung transplant is more than 80% at one year, almost 70% at three years, and more than 55% at five years. Double-lung transplants have similar success rates: 82% at one year, 64% at three years, and 48% at five years. A successful outcome is highly dependent on the patient's general medical condition. Those who have symptomatic **osteoporosis** (severe disease of the musculoskeletal system) or are users of **corticosteroids** may not have favorable outcomes.

The death rate occurs due to infections (pulmonary infections) or chronic rejection (**bronchiolitis** obliterans) if the donor lung was not a perfect genetic match. Patients are given postoperative **antibiotics** to prevent bacterial infections during the early period following surgery.

Bacterial **pneumonia** is usually severe. A bacterial genus known as *Pseudomonas* accounts for 75% of post-transplant pneumonia cases. Patients can also acquire viral and **fungal infections**, and an infection caused by a cell parasite known as *Pneumocystis carinii*. Infections are treated with specific medications intended to destroy the invading microorganism. Viral infections require treatment of symptoms.

Acute (quick onset) rejection is common within the first weeks after lung transplantation. Acute rejection is treated with **steroids** (bolus given intravenously), and is effective in 80% of cases. Chronic rejection is the most common problem, and typically begins with symptoms of **fatigue** and a vague feeling of illness. Treatment is difficult, and the results are unrewarding. There are several immunosuppressive protocols currently utilized for cases of chronic rejection. The goal of immunosuppressive therapy is to prevent the host's immune reaction from destroying the genetically foreign organ.

Preparation

The surgeon may use two common incisional approaches: sternotomy (incision through and down the breastbone) or via the side of the chest (thoracotomy).

An operative procedure known as video-assisted thoracoscopic surgery (VATS) is minimally invasive. During VATS, a lung is collapsed and the thoracoscope and surgical instruments are inserted into the thorax through any of three or four small incisions in the chest wall.

Another approach involves the use of a mediastinoscope or bronchoscope to visualize the internal anatomical structures during thoracic surgery or diagnostic procedures.

Preoperative evaluation for most patients (except emergency cases) must include cardiac tests, blood chemistry analysis, and **physical examination**. Like most operative procedures, the patient should not eat or drink food 10–12 hours prior to surgery. Patients who undergo thoracic surgery with the video-assisted approach tend to have shorter inpatient hospital stays.

Aftercare

Patients typically experience severe **pain** after surgery, and are given appropriate pain medications. In uncomplicated cases, chest and urine (Foley catheter) tubes are usually removed within 24–48 hours. A highly trained and comprehensive team of respiratory therapists and nurses is vital for postoperative care that results in improved lung function via deep breathing and coughing exercises.

Risks

Precautions for thoracic surgery include coagulation blood disorders (disorders that prevent normal blood clotting) and previous thoracic surgery. Risks

KEY TERMS

Diaphragm—A membrane in the thorax that moves to assist the breathing cycle.

Dyspnea—Difficulty breathing.

Hemothorax—Blood in the pleural cavity.

Mediastinum—The portion of the thorax that consists of the heart, thoracic parts of the great vessels, and thoracic parts of the trachea, esophagus, thymus, and lymph nodes.

include hemorrhage, myocardial infarction (**heart attack**), **stroke**, nerve injury, **embolism** (blood clot or air bubble that obstructs an artery), and infection. Total lung collapse can occur from fluid or air accumulation, as a result of chest tubes that are routinely placed after surgery for drainage.

Thoracoscopy

Definition

Thoracoscopy is the insertion of an endoscope, a narrow–diameter tube with a viewing mirror or camera attachment, through a very small incision (cut) in the chest wall.

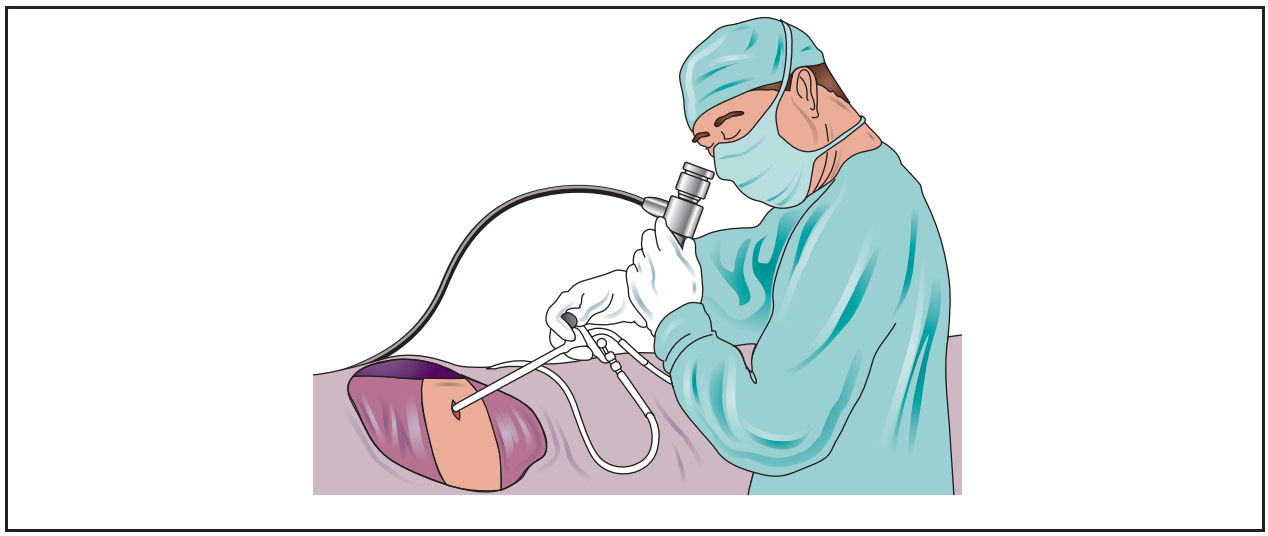
Purpose

Thoracoscopy makes it possible for a physician to examine the lungs or other structures in the chest cavity, without making a large incision. It is an alternative to thoracotomy (opening the chest cavity with a large incision). Many surgical procedures, especially taking tissue samples (biopsies), can also be accomplished with thoracoscopy. The procedure is done to:

- assess lung cancer
- take a biopsy for study
- determine the cause of fluid in the chest cavity
- introduce medications or other treatments directly into the lungs
- treat accumulated fluid, pus (empyema), or blood in the space around the lungs

For many patients, thoracoscopy replaces thoracotomy. It avoids many of the complications of open chest surgery and reduces **pain**, hospital stay, and recovery time.

WWW.BOOKBAZ.IR



Thoracoscopy is a procedure in which a physician can view the chest cavity and the lungs by inserting an endoscope through the chest wall. Thoracoscopy is less evasive than surgical lung biopsy. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Precautions

Because one lung is partially deflated during thoracoscopy, the procedure cannot be done on patients whose lung function is so poor that they do not receive enough oxygen with only one lung. Patients who have had previous surgery that involved the chest cavity, or who have blood clotting problems, are not good candidates for this procedure.

Thoracoscopy gives physicians a good but limited view of the organs, such as lungs, in the chest cavity. Endoscope technology is being refined every day, as is what physicians can accomplish by inserting scopes and instruments through several small incisions instead of making one large cut.

Description

Thoracoscopy is most commonly performed in a hospital, and general **anesthesia** is used. Some of the procedures are moving toward outpatient services and local anesthesia. More specific names are sometimes applied to the procedure, depending on the target site of the effort. For example, if a physician intends to examine the lungs, the procedure is often called pleuroscopy. The procedure takes two to four hours.

The surgeon makes two or three small incisions in the chest wall, often between the ribs. By making the incisions between the ribs, the surgeon minimizes damage to muscle and nerves and the ribs themselves. A tube is inserted in the trachea and connected to a ventilator, which is a mechanical device that assists the patient with inhaling and exhaling.

The most common reason for a thoracoscopy is to examine a lung that has a tumor or a metastatic growth of cancer. The lung to be examined is deflated to create a space between the chest wall and the lung. The patient breathes with the other lung with the assistance of the ventilator.

A specialized endoscope, or narrow–diameter tube, with a video camera or mirrored attachment, is inserted through the chest wall. Instruments for taking necessary tissue samples are inserted through other small incisions. After tissue samples are taken, the lung is reinflated. All incisions except one are closed. The remaining open incision is used to insert a drainage tube. The tissue samples are sent to a laboratory for evaluation.

Preparation

Prior to thoracoscopy, the patient will have several routine tests, such as blood, urine and chest x ray. Older patients must have an electrocardiogram (a trace record of the heart activity) because the anesthesia and the lung deflation put a big load on the heart muscle. The patient should not eat or drink from midnight the night before the thoracoscopy. The anesthesia used can cause **vomiting**, and, because anesthesia also causes the loss of the gag reflex, a person who vomits is in danger of moving food into the lungs, which can cause serious complications and death.

KEY TERMS

Endoscope—Instrument designed to allow direct visual inspection of body cavities, a sort of microscope in a long access tube.

Thoracotomy—Open chest surgery.

Trachea—Tube of cartilage that carries air into and out of the lungs.

Aftercare

After the procedure, a chest tube will remain in one of the incisions for several days to drain fluid and release residual air from the chest cavity. Hospital stays range from two to five days. Medications for pain are given as needed. After returning home, patients should do only light lifting for several weeks.

Risks

The main risks of thoracoscopy are those associated with the administration of general anesthesia. Sometimes excessive bleeding, or hemorrhage, occurs, necessitating a thoracotomy to stop it. Another risk comes when the drainage tube is removed, and the patient is vulnerable to lung collapse (pneumothorax).

Threadworm infection

Definition

Threadworm infection is an intestinal disease, which occasionally spreads to the skin, caused by a type of parasitic roundworm (helminth). In untreated patients, the disease has a high rate of reinfection caused by worms already present in the body. This type of disease recurrence is called autoinfection. Because of autoinfection, threadworms can remain inside humans for as long as 45 years after the initial infestation.

Description

Threadworm infection, which is also called strongyloidiasis, occurs in most countries of the world but is natural to (endemic in) tropical and subtropical climates. Strongyloidiasis is less common than other parasitic infections but may affect as much as 25% of the population in some developing countries. In the United States, threadworm infection is most likely to be found among immigrants; returning travelers or military personnel; people who live in parts of Appalachia and the southeastern states; and persons in group homes and similar institutions.

Human beings are universally susceptible to threadworm infection, although adults and older children are at greater risk of infection than younger children. The disease does not confer immunity. In addition to humans, threadworms can infect dogs, cats, horses, pigs, rats, and monkeys.

Causes and symptoms

Threadworm infection is caused by *Strongyloides stercoralis*, a roundworm that lives in soil and can survive there for several generations. Mature threadworms may grow as long as 1–2 in. (2–5 cm). The larvae have two stages in their life cycle: a rod-shaped (rhabdoid) first stage that is not infective; and a threadlike (filariform) stage, in which the larvae can penetrate intact human skin and internal tissues.

The infection is most commonly transmitted when a person comes into contact—usually by walking barefoot—with soil containing *S. stercoralis* larvae in their filariform stage. The threadlike larvae penetrate the skin, enter the lymphatic system, and are carried by the blood to the lungs. Once in the lungs, the larvae burst out of the capillaries into the patient's main respiratory system. They migrate upwards, usually without symptoms, to the patient's throat, where they are swallowed and carried down into the digestive tract. The filariform larvae settle in the small intestine. They mature into adults that deposit eggs that hatch, usually in the intestines, into noninfectious rhabdoid larvae. The rhabdoid larvae then migrate into the patient's large intestine and are excreted in the feces. The time from initial penetration of the skin to excretion is 17–28 days. The rhabdoid larvae metamorphose into the infective filariform stage in the soil.

WWW.BOOKBAZ.IR

Threadworms are unique among human parasites in having both free-living and parasitic forms. In the free-living life cycle, some rhabdoid larvae develop into adult worms that live in contaminated soil and produce eggs that hatch into new rhabdoid larvae. The adult worms may live as long as five years.

The signs and symptoms of threadworm infection vary according to the stage of the disease as the larvae migrate throughout the body. Patients who have autoinfection may have chronic or intermittent symptoms for years after they are first infected.

Skin

The filariform larvae usually enter the body through the skin of the feet. There may be swelling, **itching**, and **hives** at the point of entry that may be confused with insect bites. Patients with chronic threadworm infection may also develop an itchy rash on their buttocks, thighs, or abdomen.

Digestive tract

Although some patients may notice only mild **diarrhea** and cramps, others may have **fever**, nausea, **vomiting**, general weakness, and blood or mucus in their stools. The **pain** may mimic a stomach ulcer.

Throat and lungs

When the larvae migrate to the lungs and air passages, the patient may have symptoms ranging from a simple dry **cough** to fever, difficulty breathing, and coughing up blood or pus.

Hyperinfection syndrome

Hyperinfection syndrome is a potentially fatal set of complications resulting from the spread of filariform larvae to the lungs and other organ systems. It can include inflammation of the heart tissue, stomach **ulcers**, perforation of the intestines, blood **poisoning**, **meningitis**, **shock**, and eventual death. Hyperinfection syndrome is most likely to occur in patients with immune disorders or **malnutrition**, or in those taking anti-inflammatory corticosteroid (anti-inflammatory) medications. It has been reported in only a few **AIDS** patients.

Autoinfection

Threadworm autoinfection in humans follows two patterns. In internal autoinfection, some rhabdoid larvae in the lower bowel develop into filariform larvae that enter the bloodstream from the intestines and migrate to the lungs. In external autoinfection, the skin around the patient's anus is infected by larvae in the feces.

KEY TERMS

Antibody—A protein molecule produced by the immune system that is specific to a disease agent, such as threadworm larvae. The severity of a patient's infection can be measured from the level of antibody in the blood.

Autoinfection—An infection caused by a disease agent that is already present in the body.

Corticosteroid—A class of drugs based on hormones formed in the adrenal gland, used to reduce inflammation. They increase the likelihood of hyperinfection syndrome in patients with threadworm infection.

Endemic—Natural to or characteristic of a particular place, population, or climate. Threadworm infections are endemic in the tropics.

Filariform—Threadlike in appearance, like the infectious stage of the threadworm larva.

Helminth—A type of parasitic worm. Threadworms belong to a subcategory of helminths called nematodes, or roundworms.

Hyperinfection syndrome—A condition of massive infection in which threadworm larvae multiply rapidly and spread throughout the body. It is usually associated with damage to the immune system, the use of steroid medications, or malnutrition.

Rhabdoid—Rod- or wand-shaped, like the first stage of the threadworm larva.

String test—A test performed to diagnose threadworm infection. The patient is asked to swallow a weighted string that absorbs stomach juices, which can be analyzed for the presence of threadworm larvae.

Diagnosis

The doctor is likely to consider a diagnosis of threadworm infection when a patient has the symptoms described earlier and a history of travel or military service in areas where the disease is endemic. A definite diagnosis is made by finding rhabdoid or filariform larvae in the patient's body fluids. The larvae may be found in fresh stool specimens or in mucus coughed up when the infection has reached the lungs. Because the larvae cannot be detected in the stools of 25% of infected patients, the string test is often performed to confirm the diagnosis. In this test, the patient swallows a weighted string which is withdrawn after four hours. The digestive juices absorbed by the string are then examined for the presence of threadworm larvae.

Doctors can also use blood tests and diagnostic imaging to support the diagnosis. Between 85% and 95% of patients with threadworm infections will have a measurable level of antibodies in their blood, even though these antibodies do not prevent the disease from spreading. In addition, patients with severe infections often have unusually high levels of white cells in their blood. X rays of the intestines or the chest often help in locating specific areas of inflamed or ulcerated tissue.

Treatment

Threadworm infections are treated with medications. The drugs most often given are ivermectin, thiabendazole (Mintezol), and albendazole. Ivermectin is generally preferred because it has fewer side effects than thiabendazole. These drugs, which are taken by mouth over a period of 2–7 days, work by preventing the development of eggs and new larvae. Patients with severe infections should be given protein replacement, blood transfusions, and fluids to replace losses from nausea, vomiting, and diarrhea.

Patients who are taking **corticosteroids** should be carefully evaluated if they have symptoms of threadworm infection, because these medications encourage the development of hyperinfection syndrome.

Prognosis

The prognosis for complete recovery is good for most patients, except those with hyperinfection syndrome or severe protein loss.

Prevention

There is no effective immunization against threadworm infection. Prevention of the disease requires careful attention to personal and institutional hygiene in endemic areas, including handwashing after defecating and before handling food. Other precautions include wearing shoes when visiting countries with high rates of threadworm infection, and monitoring close contacts of patients for signs of infection.

Throat culture

Definition

A throat culture is a technique for identifying disease bacteria in material taken from the throat. Most throat cultures are done to rule out infections caused by beta-hemolytic streptococci, which cause **strep throat**. Hemolytic means that these streptococci destroy red blood cells.

Purpose

The primary purpose of a throat culture is identification of the specific organisms that cause strep throat. These organisms are Group A streptococci, specifically *Streptococcus pyogenes*. Since most sore throats are caused by viral infections rather than by *S. pyogenes*, a correct diagnosis is important to prevent unnecessary use of **antibiotics** and to begin treatment of strep infections as soon as possible. Group A **streptococcal infections** are potentially life-threatening, often involving other parts of the body in addition to the throat. Besides causing **sore throat** (pharyngitis), streptococci can also cause **scarlet fever**, **rheumatic fever**, **kidney disease**, or abscesses around the tonsils.

Throat cultures can also be used to identify other disease organisms that are present in the patient's throat, and to identify people who are carriers of the organisms that cause **meningitis** and whooping **cough**.

This nurse is taking a throat culture from a patient for laboratory analysis. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

Besides their use in diagnosis, throat cultures are sometimes used to test antibiotics for their effectiveness in treating different infections.

Precautions

Throat cultures should be taken before the patient is given any antibiotic medications. In addition, the patient's immunization history should be checked to evaluate the possibility that diseases other than strep are causing the sore throat. The care provider should wash the hands carefully after taking the specimen to prevent the spread of any infectious organisms.

Description

A throat culture test should be done on anyone who has symptoms of a strep throat. These symptoms include a sore throat that may be accompanied by a **fever**, body aches, and loss of appetite. Age is a consideration, in that strep throat is more common in children than in adults. The tonsils and the back of the throat often appear red, swollen, and streaked with pus. These symptoms usually appear 1–3 days after being exposed to group A strep. Because strep is highly contagious, family members and close contacts of patients diagnosed with strep throat should also have throat cultures performed if they show signs of the disease.

The specimen for throat culture is obtained by wiping the patient's throat with a cotton swab. The patient is asked to tilt the head back and open the mouth wide. With the tongue depressed and the patient saying "ah," the care provider wipes the back of the throat and the tonsils with a sterile swab. The swab is applied to any area that appears either very red or discharging pus. The swab is removed gently without touching the teeth, gums, or tongue. It is then placed in a sterile tube for immediate delivery to a laboratory. Obtaining the specimen takes less than 30 seconds. Laboratory results are usually available in 2–3 days. The swabbing procedure may cause gagging but is not painful. The doctor makes a note for the laboratory to indicate if any disease organisms other than strep are suspected, because some require special growth conditions in the laboratory.

S. pyogenes is cultured on a growth medium called blood agar. Agar is a gel that is made from the cell walls of red algae. Blood agar is made from agar gel and sheep's blood. When the throat swab reaches the laboratory, it is wiped across a blood agar plate. The plate is allowed to incubate for 24–48 hours to allow the growth of bacteria. If the organism is a Group A hemolytic streptococcus, the area immediately around the bacterial colony will be cleared of red blood cells.

KEY TERMS

Agar—A gel made from red algae that is used to culture certain disease agents in the laboratory.

Antibiotic—A drug given to stop the growth of bacteria. Antibiotics are ineffective against viruses.

Antigen—A substance that interacts with an antibody and causes an immune reaction.

Carrier—A person harboring an infectious disease who may be immune to it but who can give it to others.

Diphtheria—A serious disease caused by a bacterium, *Corynebacterium diphtheriae*.

Hemolytic—Able to dissolve red blood cells. The bacteria that cause strep throat are hemolytic organisms.

Streptococcus—A category (genus) of sphere-shaped bacteria that occur in pairs or chains.

Thrush—A disease occurring in the mouth or throat that is caused by a yeast, *Candida albicans*.

Whooping cough—An infectious disease of the respiratory tract caused by a bacterium, *Bordetella pertussis*.

Hemolytic streptococci dissolve (lyse) red blood cells, leaving a clear zone surrounding the colony.

Alternative procedures

Instant strep tests are now available to help diagnose strep throat. They can be used in the doctor's office and take about 10–30 minutes to perform. Instant tests detect an antigen associated with the streptococcus. These tests are relatively new and not available at all clinics. Their reliability has improved since they were first introduced. If an instant throat test is negative, a standard throat culture can be performed to verify the results.

Preparation

The patient does not need to avoid food or fluids before the test. Recent gargling or treatment with antibiotics, however, will affect the culture results. The laboratory should be notified if the patient has been recently taking antibiotic medications.

Aftercare

No specific aftercare is needed.

Risks

There is a minor risk for the health professional of exposure to the patient's illness.

Results

Normal results would include finding organisms that grow in healthy throat tissues. These organisms include non-hemolytic and alpha-hemolytic streptococci, some *Neisseria* species, staphylococci, **diphtheria** and hemophilus organisms, pneumococci, yeasts, and Gram-negative rods.

Abnormal results

In addition to *S. pyogenes*, other disease agents may be identified in the throat culture. Infectious agents that can be identified include *Candida albicans*, which can cause thrush; *Corynebacterium diphtheriae*, which can cause diphtheria; and *Bordetella pertussis*, which can cause whooping cough. In addition, the appearance of a normal organism in very high numbers may also be regarded as an abnormal result.

Thrombocytopenia

Definition

Thrombocytopenia is an abnormal drop in the number of blood cells involved in forming **blood clots**. These cells are called platelets.

Description

Thrombocytopenia is a blood disease characterized by an abnormally low number of platelets in the bloodstream. The normal amount of platelets is usually between 150,000 and 450,000 cells per microliter of blood. A microliter is an amount equal to one one-millionth of a liter (a liter is almost equal to a quart). Platelet numbers are counted by having a blood sample collected and placing a measured amount of blood in a machine called a cell counter. When the platelet number drops below 150,000 cells per microliter of blood, this person is said to be thrombocytopenic.

KEY TERMS

Gamma globulin—One of a group of proteins found in the blood that is involved in helping the body fight infections.

Stent—A man-made surgical device, usually tube-shaped, that is placed into a blood vessel to keep it from closing.

Transfusion—The transfer of blood from one person to another. Transfusions can be direct, in which blood is transferred from the donor to the recipient; or indirect, in which the blood is taken from the donor, stored in a container, and then given to the recipient.

Causes and symptoms

Abnormal reductions in the number of platelets are caused when abnormalities occur in any of the following three processes: decreased platelet production by the bone marrow; increased trapping of platelets by the spleen; or a more rapid than normal destruction of platelets. Persons with this condition easily bruise and can have episodes of excess bleeding (a hemorrhage).

Platelets come from megakaryocytes, which are produced in the material located within the center cavity of the bones (bone marrow). When abnormalities develop in the marrow, the marrow cells can lose their ability to produce platelets in correct amounts. The result is a lower than normal level of platelets in the blood. Drugs used in cancer **chemotherapy** can cause the marrow to malfunction in this way, as can the presence of tumor cells in the marrow itself.

Normally, the spleen holds about one-third of the body's platelets as part of this organ's function to recycle **aging** or damaged red blood cells (the cells that carry oxygen in the blood). When **liver disease** or cancer of the spleen is present, the spleen can enlarge, resulting in a greater number of platelets staying in the organ. This condition results in abnormally low numbers of platelets in the blood.

Platelets can break down in unusually high amounts in persons with abnormalities in their blood vessel walls; with blood clots; or with man-made replacement heart valves. Devices placed inside

WWW.BOOKBAZ.IR

blood vessels to keep them from closing (stents) due to weakened walls or fat build-up can also cause platelets to break down. In addition, infections and other changes in the immune system can speed up the removal of platelets from the circulation.

Diagnosis

Thrombocytopenia is diagnosed by having a blood sample taken and counting the platelets present in the sample. However, accurately determining the medical reason for this conditions is complex.

Once a low **platelet count** is verified, a careful evaluation of the function of the bone marrow and spleen are necessary. Improper functioning of either or both of these organs can cause thrombocytopenia. In addition, the causes for the abnormal spleen or marrow function must be investigated since different cancers, blood disorders, or liver disease can be the true cause for the drop in platelets found in the blood.

Treatment

If low platelet counts are caused by an enlarged spleen, removal of the spleen can help raise the platelet level, since the spleen is no longer there to capture the platelets. Proper treatment for what causes the enlarged spleen is necessary as well.

Low platelet counts can indicate more serious conditions. If a dysfunctional immune system is found to be the cause for this condition, drugs like **steroids** or **gamma globulin** can be used to help maintain platelet levels in certain cases.

If low platelet levels are due to an abnormally low level of platelet production, transfusions of platelets can be given as well.

Prognosis

Thrombocytopenia can result in fatal bleeding, but it also can indicate various other, more serious, cancers and disorders that affect the blood cells. This condition requires thorough medical evaluation.

Prevention

There is no known way to prevent hrombocytopenia.

Thrombocytosis

Definition

Thrombocytosis is a blood disorder in which the body produces a surplus of platelets (thrombocytes).

Description

Thrombocytosis is an abnormally increased number of platelets in the blood. Platelets are blood cells that stick together, helping blood to clot. Thrombocytosis is a condition that may have many causes.

Throbocytosis is classified as one of two types. Secondary thrombocytosis can be traced to another cause, such as inflammation, severe bleeding, iron deficiency, or some cancers. Primary thrombocytosis (or essential thrombocythemia) is a single disease entity, with unique clinical characteristics.

Causes and symptoms

The cause of essential thrombocytosis is unknown.

Secondary thrombocytosis may develop as a result of:

- acute hemorrhage or infection
- anemia
- arthritis and other chronic inflammations
- cancer
- exercise
- iron deficiency
- medication
- osteoporosis
- removal of the spleen (splenectomy)
- polycythemia vera (a disorder affecting other red blood cells, as well as platelets)
- stress
- surgery

Symptoms

Two of every three patients who have thrombocytosis do not have any symptoms of the disease at the time of diagnosis. Younger patients may remain symptom-free for years.

Enlargement of the spleen is detected in 60% of patients with thrombocytosis. The liver may also be enlarged. As many as half of all patients experience bleeding from the skin, gums, or nose; and 20–50% have some blockage of veins or arteries.

Other symptoms of thrombocytosis include:

- bloody stools

- bruising
- dizziness
- headache
- hemorrhage
- prolonged bleeding after having surgery or after having a tooth pulled
- redness or tingling of the hands and feet
- weakness; in rare instances, the lymph nodes become enlarged

The highest platelet counts usually produce the most severe symptoms. Younger patients (especially women) may not have symptoms, even though their platelet counts are very high.

Complications

Complications of thrombocytosis include **stroke**, **heart attack**, and formation of **blood clots** in the arms and legs.

A doctor should be notified whenever bleeding is unexplained or prolonged or the patient develops:

- chest or leg pain
- confusion
- numbness
- weakness

Diagnosis

The patient's symptoms suggest the presence of thrombocytosis. Blood tests confirm the diagnosis.

Bone marrow aspiration (removal of a tissue sample for microscopic examination) may also be performed.

Treatment

The key to treating secondary thrombocytosis is treating the underlying condition.

Any patient who has thrombocytosis should be encouraged not to smoke.

In young people who have no symptoms, this condition can remain stable for many years. These patients should be monitored by a physician, but may not require treatment.

Treatment for patients who do have symptoms focuses on controlling bleeding, preventing the formation of blood clots, and lowering platelet levels. Treatment for secondary thrombocytosis involves treating the condition or disease responsible for excess platelet production.

In 1997, the U.S. Food and Drug Administration (FDA) approved the use of anagrelide HCl (Agrylin) to reduce elevated platelet counts and decrease the risk of clot formation. Some patients have benefited from the use of hydroxyurea, an anti-cancer drug.

Low doses of **aspirin** may prevent clotting, but can cause serious hemorrhages.

If drug therapy does not bring platelet counts down to an acceptable level as rapidly as necessary, plateletpheresis may be performed. Usually combined with drug therapy and used primarily in medical emergencies, this procedure consists of:

- withdrawing blood from the patient's body
- removing platelets from the blood
- returning the platelet-depleted blood to the patient

Prognosis

Many patients with thrombocytosis remain free of complications for long periods. However, some patients may die as a result of blood clots or uncontrolled bleeding.

Prevention

There is no known way to prevent thrombocytosis.

Thrombolytic therapy

Definition

Thrombolytic therapy is the use of drugs that dissolve **blood clots**.

Purpose

When a blood clot forms in a blood vessel, it may cut off or severely reduce blood flow to parts of the body that are served by that blood vessel. This can cause serious damage to those parts of the body. If the clot forms in an artery that supplies blood to the heart, for example, it can cause a **heart attack**. A clot that cuts off blood to the brain can cause a **stroke**. Thrombolytic therapy is used to dissolve blood clots that could cause serious, and possibly life-threatening,

WWW.BOOKBAZ.IR

damage if they are not removed. Research suggests that when used to treat stroke, thrombolytic therapy can prevent or reverse **paralysis** and other problems that otherwise might result.

Thrombolytic therapy also is used to dissolve blood clots that form in tubes put into people's bodies for medical treatments, such as dialysis or **chemotherapy**.

Description

Thrombolytic therapy uses drugs called thrombolytic agents, such as alteplase (Activase), anistreplase (Eminase), streptokinase (Streptase, Kabikinase), urokinase (Abbokinase), and tissue plasminogen activator (TPA) to dissolve clots. These drugs are given as injections, only under a physician's supervision.

Recommended dosage

The physician supervising thrombolytic therapy decides on the proper dose for each patient. He or she will take into account the type of drug, the purpose for which it is being used, and in some cases, the patient's weight.

Precautions

For thrombolytic therapy to be effective in treating stroke or heart attack, prompt medical attention is very important. The drugs must be given within a few hours of the beginning of a stroke or heart attack. However, this treatment is not right for every patient who has a heart attack or a stroke. Only a qualified medical professional can decide whether a thrombolytic agent should be used. To increase the chance of survival and reduce the risk of serious, permanent damage, anyone who has signs of a heart attack or stroke should get immediate medical help.

Thrombolytic therapy may cause bleeding. Usually this is not serious, but severe bleeding does occur in some people. This is especially likely in older people. To lower the risk of serious bleeding, people who are given this drug should move around as little as possible and should not try to get up on their own unless told to do so by a healthcare professional. Following all the instructions of the healthcare providers in charge is very important.

Thrombolytic therapy may be more likely to cause serious bleeding in people who have certain medical conditions or have recently had certain medical procedures. Before being given a thrombolytic agent, anyone with any of these problems or conditions should tell the physician in charge about it:

- blood disease or current or past bleeding problems in any part of the body
- heart or blood vessel disease
- stroke (recent or in the past)
- high blood pressure
- brain tumor or other brain disease
- stomach ulcer or colitis
- severe liver disease
- active tuberculosis
- recent falls, injuries, or blows to the body or head
- recent injections into a blood vessel
- recent surgery, including dental surgery
- tubes recently placed in the body for any reason
- recent delivery of a baby

In addition, anyone who has had a recent streptococcal (strep) infection should tell the physician in charge. Some thrombolytic agents may not work properly in people who have just had a strep infection, so the physician may want to use a different drug.

People who take certain medicines may be at greater risk for severe bleeding when they are given a thrombolytic agent.

Women who are pregnant should tell the physician in charge before being given a thrombolytic agent. There is a slight chance that a woman who is given thrombolytic therapy during the first five months of **pregnancy** will have a **miscarriage**. However, streptokinase and urokinase have both been used without problems in pregnant women.

After being treated with thrombolytic therapy, women who are **breastfeeding** should check with their physicians before starting to breastfeed again.

Side effects

Anyone who has **fever** or who notices bleeding or oozing from their gums, from cuts, or from the site where the thrombolytic agent was injected should immediately tell their healthcare provider.

People who are given thrombolytic therapy should also be alert to the signs of bleeding inside the body and should check with a physician immediately if any of the following symptoms occur:

- blood in the urine
- blood or black, tarry stools
- constipation
- coughing up blood
- vomiting blood or material that looks like coffee grounds

KEY TERMS

Arteries—Blood vessels that carry blood away from the heart to the cells, tissues, and organs of the body.

Blood clot—A hard mass that forms when blood gels.

Chemotherapy—Treatment of an illness with chemical agents. The term is usually used to describe the treatment of cancer with drugs.

Dialysis—A process used in people whose kidneys are not working well. By way of a filtering machine, dialysis separates waste and other useless materials from the blood – a job the kidneys usually do.

Paralysis—Loss of the ability to move one or more parts of the body.

Stroke—A serious medical event in which blood flow to the brain is stopped. This may be because of a blood clot in an artery or because an artery has burst. Strokes may cause paralysis and changes in speech, memory, and behavior.

- nosebleeds
- unexpected or unusually heavy vaginal bleeding
- dizziness
- sudden, severe, or constant headaches
- pain or swelling in the abdomen or stomach
- back pain or backache
- severe or constant muscle pain or stiffness
- stiff, swollen, or painful joints

Other side effects of thrombolytic agents are possible. Anyone who has unusual symptoms during or after thrombolytic therapy should tell a healthcare professional.

Interactions

People who take certain medicines may be at greater risk for severe bleeding when they receive a thrombolytic agent. Anyone who is given a thrombolytic agent should tell the physician in charge about all other prescription or nonprescription (over-the-counter) medicines he or she is taking. Among the medicines that may increase the chance of bleeding are:

- aspirin and other medicines for pain and inflammation
- blood thinners (anticoagulants)
- antiseizure medicines, such as Depakote (divalproex) and Depakene (valproic acid)
- cephalosporins, such as cefamandole (Mandol), cefoperazone (Cefobid), and Cefotetan (Cefotan)

Also, anyone who has been treated with anistreplase or streptokinase within the past year should tell the physician in charge. These drugs may not work properly if they are given again, so the physician may want to use a different thrombolytic agent.

Thrombophlebitis

Definition

Thrombophlebitis is inflammation of a vein with blood clot formation inside the vein at the site of the inflammation. Thrombophlebitis also is known as phlebitis, phlebothrombosis, and venous thrombosis.

Demographics

Thrombophlebitis can occur in both deep veins and superficial veins, but most often occurs in superficial veins of the extremities (legs and arms). Most cases occur in the legs.

Description

There are two parts to thrombophlebitis, inflammation of a vein and blood clot formation. If the inflammation is minor, the disease usually is called venous thrombosis or phlebothrombosis. When thrombophlebitis occurs in a superficial vein, one that is near the surface of the skin and is visible to the eye, the disease is called superficial thrombophlebitis. Any form of injury to a blood vessel can result in thrombophlebitis. In the case of superficial thrombophlebitis, the blood clot usually attaches firmly to the wall of the affected vein. Since superficial blood veins do not have muscles that massage the veins, **blood clots** in superficial veins tend to remain where they form and seldom break loose. When thrombophlebitis occurs in a deep vein, a vein that runs deep within muscle tissue, it is called deep venous thrombosis. Deep venous thrombosis presents the threat of producing blood clots that will break loose to form emboli. These emboli can lodge in other tissues where they can block the blood supply, typically in the lungs. This condition results in tissue damage and can sometimes be serious or fatal, for example, **pulmonary embolism**.

WWW.BOOKBAZ.IR

KEY TERMS

Emboli, embolus—Emboli is the plural form of embolus. Embolus is any mass of air, blood clot, or foreign body that travels through the bloodstream and is capable of lodging in smaller blood vessels where it can obstruct blood flow to that vessel.

Embolism—The obstruction of a blood vessel by a blot clot.

Phlebitis—Inflammation of a vein.

Thrombus—A blood clot that forms within a blood vessel or the heart.

Causes and symptoms

The main symptoms are tenderness and **pain** in the area of the affected vein. Redness and/or swelling also may be seen. In the case of deep venous thrombosis, there is more swelling than is caused by superficial thrombophlebitis, and the patient may experience muscle stiffness in the affected area. There are many causes of thrombophlebitis.

The main causes can be grouped into three categories: injury to blood veins, increased blood clotting, and blood stasis. When blood veins are damaged, collagen in the blood vein wall is exposed. Platelets respond to collagen by initiating the clotting process. Damage to a vein can occur as a consequence of indwelling catheters, **trauma**, infection, Buerger's disease, or the injection of irritating substances. Increased tendency of the blood to clot can be caused by malignant tumors, genetic disorders, and **oral contraceptives**, though newer generation birth control pills carry a lower risk for many women. Stasis, in which the blood clots due to decreased blood flow in an area, can happen following surgery, as a consequence of **varicose veins**, as a complication of postpartum states, and following prolonged bed rest. In the case of prolonged bed rest, blood clots form because of inactivity, which allows blood to move sluggishly and stagnate (collect) in blood veins. This condition can lead to blood clots. These clots (also called emboli) sometimes are released when the patient stands up and resumes activity. This can present a problem if the emboli lodge in vital organs. In the case of postpartum patients, a **fever** developing 4–10 days after delivery may indicate thrombophlebitis. A 2004 study revealed that postmenopausal women taking hormone therapy combining estrogen and progestin had more than a two–fold higher risk of venous thrombosis than non–hormone users.

Diagnosis

In superficial thrombophlebitis, the location of the clot sometimes can be seen by the unaided eye. Blood clots are hard and can usually be detected by a physician using palpation (touching or massage). Deep venous thrombosis requires specialized diagnostic procedures to detect the blood clot. Among the exams a physician may use are **ultrasound** and x ray, coupled with dye injection (venogram).

Treatment

Superficial thrombophlebitis usually resolves without treatment. If treatment of superficial thrombophlebitis is given, it usually is limited to the application of heat or anti–inflammatory drugs, such as **aspirin** or ibuprofen, which also help to relieve the pain. It can take from several days to several weeks for the clot to resolve and the symptoms to completely disappear. A 2003 study showed that low intensity therapy with warfarin, a common blood thinner, prevented recurrent venous thromboembolism in study subjects. A newer anticoagulant called ximelagatran also has been shown as equally or more effective than warfarin in preventing **deep vein thrombosis**.

Deep venous thrombosis is a serious condition, treated with **anticoagulant drugs** and by keeping the affected limb elevated. The primary objective in treating deep venous thrombosis is prevention of a pulmonary **embolism**. The patient usually is hospitalized during initial treatment. The prescribed anticoagulant drugs limit the ability of blood clots to grow and new clots to form. Sometimes, a drug that dissolves blood clots is administered. These drugs must be used with caution because, as the clot dissolves, it may break loose from the site where it formed and become an embolus. Surgery may be used if the affected vein is likely to present a long–term threat of producing blood clots that will release emboli. When superficial thrombophlebitis occurs in the groin, where the superficial veins join the deep veins, the threat of emboli is present. In this case, blood clots formed in the superficial veins can extend into the much larger deep vein where they break off and are released into the bloodstream. The affected veins are either removed or tied off to prevent the release of blood clots. Tying off superficial blood veins is an outpatient procedure that can be performed with local **anesthesia**. The patient is capable of immediately resuming normal activities.

Prognosis

Superficial thrombophlebitis seldom progresses to a serious medical complication, although non–lethal

embolisms may be produced. Deep venous thrombosis may lead to embolism, especially pulmonary embolism. This is a serious consequence of deep venous thrombosis, and sometimes is fatal.

Thrombotic thrombocytopenic purpura

Definition

Thrombotic thrombocytopenic purpura (TTP) is a rare blood disorder that causes clots to form in blood vessels throughout the body.

Description

Several types of cells circulate in the blood: white blood cells, red blood cells, and platelets. The platelets are blood cell fragments that help to form clots to stop bleeding. In people who have TTP, **blood clots** can form in small blood vessels, even when there is no injury. These small clots can cause several uncomfortable and serious symptoms and medical complications, such as **stroke**, seizure, or problems with kidney function.

When platelets gather to form unnecessary clots, there are too few left in the rest of the bloodstream, leading to **thrombocytopenia**, or low platelet counts in the circulating blood. Thrombocytopenia can cause people to bleed longer than normal after cuts or to bleed just under the skin, which shows up as small violet areas called purpura. The bleeding under the skin also can cause reddish or purple dots on the surface of the skin that resemble a rash. These dots are called petechiae.

TTP also affects red blood cells. The disorder causes red blood cells to break down more quickly than the body can replace them, resulting in **hemolytic anemia**. This rare form of anemia causes additional symptoms and requires treatment.

Patient with a purplish, brownish discoloration on the leg known as a purpura. *(Mediscan/Medical-on-Line/Alamy Limited)*

WWW.BOOKBAZ.IR

Demographics

TTP is a rare blood disorder. Only about one case is diagnosed per 100,000 people in the United States each year. It has been difficult to obtain accurate estimates of the disorder, but it is certain that the disorder is more common in women than men, although the reasons for higher incidence in women are unknown.

Causes and symptoms

TTP can be inherited or acquired. A gene has been identified that is associated with both forms of the disease. A gene called ADAMTS13 instructs an enzyme that controls normal blood clotting activity. If the ADAMTS13 gene is mutated, the enzyme does not work as it should, leading to the clotting problems associated with TTP. Other genetic or environmental factors could also play a role in causing TTP or how much the disorder affects each person who has it.

Causes

Individuals may inherit TTP from their parents or acquire it, meaning they develop the condition anytime after birth. In inherited TTP, the mutated gene is passed from a parent to a child. Inherited forms include familial TTP or Upshaw-Schulman syndrome. Acquired forms of the disease include Moschcowitz disease or microangiopathic hemolytic anemia. In the acquired form, a person does not have the mutated gene. Acquired TTP almost always occurs in adults. TTP also may be caused by **hemolytic-uremic syndrome**. This blood disorder is similar to TTP but most often occurs in children and likely has different causes. Environmental factors can trigger the clotting problems and complications of TTP in a person who has the faulty gene. Examples include having surgery, a major infection, cancer, or being pregnant. Certain **chemotherapy** drugs and some hormone therapy also can trigger TTP.

Symptoms

Symptoms of TTP occur from the various problems the disorder causes in a person's blood, including blood clots in the vessels, too few platelets in the circulating blood, and damage to red blood cells. Signs and symptoms include:

- purpura, or purplish bruises on the skin and in the mouth
- fever
- jaundice or paleness
- weakness from anemia and shortness of breath
- headache
- nausea
- petechiae, tiny pinpoint red or purple dots on the skin

Diagnosis

A doctor asks about medical history, such as medications that have been taken and recent infections. Family history also is important in diagnosing inherited TTP. The doctor performs a **physical examination** to look for signs of TTP, such as purpura or petachiae. If the doctor suspects TTP, several tests may be recommended to confirm a diagnosis.

Tests

A blood test called a **complete blood count** (CBC) measures the number of each type of blood cell in a person's blood from a small blood sample. A person who has TTP has a normal or slightly high **white blood cell count** and a lower number of platelets than normal (about 20,000–50,000 per microliter). A small amount of blood will be placed on a slide to examine under a microscope or run through a machine in the laboratory for a test called a blood smear. The test can more closely examine blood cells and reveal possible damage to red blood cells, which helps confirm TTP. A Coombs test can help doctors tell whether TTP is the cause of hemolytic anemia. Blood samples also can be checked with special techniques for signs of ADAMTS13 enzyme activity.

Other tests may be used to help determine complications of TTP and help a doctor plan treatment. For example, the death of blood cells caused by TTP increased bilirubin in the blood. High levels of bilirubin can cause **jaundice**, and the doctor may check bilirubin levels with a blood test. TTP can affect the kidneys, which can be determined with urine tests or tests of kidney function. Urine tests may show blood cells in urine, high levels of protein, or high levels of a substance called creatinine that is removed by the kidneys.

Treatment

Individuals with TTP require treatment to prevent worsening complications; often, a diagnosis of TTP is considered a medical emergency that requires immediate treatment. In general, a person with TTP is cared for by a hematologist and immediately placed on plasma therapy to replace missing or mutated ADAMTS14 enzymes. Plasma is the liquid portion of the blood. The preferred therapy usually is plasma

KEY TERMS

Hematologist—A doctor who specializes in studying and treating diseases of the blood.

Hemolytic anemia—A condition in which the body lacks healthy red blood cells, usually when the cells are being destroyed because of a disease or condition.

Petachiae—Tiny red or purplish dots the size of a pin that appear on the skin or in the mouth and resemble a rash. They are caused by bleeding just under the skin.

Plasmapheresis—Plasma exchange, or the removal of the liquid portion of the blood, separating it from blood cells and returning the cells with healthy plasma.

exchange with fresh frozen plasma. Also called **plasmapheresis**, the treatment works by removing blood from the patient through an intravenous (IV) needle and running the blood through a tube and into a cell separator, which removes plasma from the blood to filter out proteins that damage the ADAMTS13 enzyme. All of the patient's blood except the plasma is saved and returned to the patient's vein along with donated plasma.

Plasmapheresis usually takes place in a hospital and takes about two hours to complete. The procedure is safe, although some patients have allergic reactions or **hypotension** (low blood pressure) during the procedure. There is a small risk of infection from blood products. If plasma exchange is not available, a patient may receive infusions of fresh frozen plasma until the patient can be transferred to a facility that has the service. More than one plasma exchange treatment often is required, and many patients need at least five exchanges in the first ten days of treatment. The doctor continues recommended treatments until symptoms improve and blood test results return to normal levels. Individuals with TTP may have flare-ups of symptoms that require returning for plasma exchange treatments from time to time.

Some patients also benefit from **corticosteroids** along with plasma, and patients who have relapses of TTP may receive a chemotherapy drug called vincristine. Although platelet levels are low in people with TTP, people who have the disorder usually should not receive transfusions of platelets unless they are in danger of serious bleeding, typically in the brain. Platelet transfusions can cause serious complications such as **heart attack** or stroke in people who have TTP.

Prognosis

Patients undergoing treatment for TTP should remain in the hospital until they begin to improve. Between 75% and 90% of patients who undergo plasma exchange therapy have a successful response. An average of 15% of patients can die from the disorder early in its course if they do not receive prompt treatment. People with TTP who are otherwise healthy have excellent 10-year survival rates.

Prevention

There is no way to prevent inherited or acquired TTP. Parents who have the disorder should communicate this information to doctors when they have children and be especially attentive to signs and symptoms in their children. People who have TTP can help prevent flare-ups by avoiding triggers such as **pregnancy** or medical procedures or medications that might cause flare-ups.

Thymoma

Definition

Thymomas are the most common tumor of the thymus.

Description

The thymus is located in the upper chest just below the neck. It is a small organ that produces certain types of white blood cells before birth and during childhood. These white blood cells are called lymphocytes and are an important part of the body's immune system. Once released from the thymus, lymphocytes travel to lymph nodes where they help to fight infections. The thymus gland becomes smaller in adulthood and is gradually taken over by fat tissue.

Although rare, thymomas are the most common type of thymic cancer. They arise from thymic epithelial cells, which make up the covering of the thymus. Thymomas frequently contain lymphocytes, which are noncancerous. Thymomas are classified as either noninvasive (previously called "benign") or invasive (previously called "malignant"). Noninvasive thymomas are those in which the tumor is encapsulated and easy to remove. Invasive thymomas have spread to nearby structures (such as the lungs) and are difficult to remove. Approximately 30–40% of thymomas are of the invasive type.

Thymoma affects men and women equally. It is usually diagnosed between the ages of 40 and 60 years. Thymomas are uncommon in children.

Causes and symptoms

The cause of thymoma is unknown. Cancer is caused when the normal mechanisms that control cell growth become disturbed, causing the cells to continually grow without stopping. This is caused by damage to the DNA in the cell.

Approximately 40% of the patients diagnosed with thymoma have no symptoms. The symptoms in the remaining 60% of patients are caused by pressure from the enlarged thymus on the windpipe (trachea) or blood vessels, or by paraneoplastic syndromes. Paraneoplastic syndromes are collections of symptoms in cancer patients that cannot be explained by the tumor. Seventy-one percent of thymomas are associated with paraneoplastic syndromes. The most common syndromes related to thymoma are pure red cell aplasia (having abnormally low levels of red blood cells), **myasthenia gravis** (a muscular disorder), and hypogammaglobulinemia (having abnormally low levels of antibodies). These conditions are autoimmune diseases—those in which the body mounts an attack against certain normal cells of the body.

Symptoms of thymoma may include:

- shortness of breath
- swelling of the face
- coughing
- chest pain
- muscle weakness (especially in the eyes, neck, and chest, causing problems with vision, swallowing, and breathing)
- weakness
- dizziness
- shortness of breath
- fatigue

Diagnosis

The physician will conduct a complete physical exam. He or she may be able to feel a fullness in the lower neck region. Routine blood tests may be performed. Imaging studies are necessary because the symptoms of thymoma can be caused by many other diseases. Thymomas can be identified by chest x ray, **magnetic resonance imaging**, and computed tomography.

A biopsy may be performed, in which a small sample of the tumor is removed and examined under the microscope. However, because of the risk of "seeding" cancerous cells, biopsies are not routinely performed. There are a few different methods to biopsy a thymoma. For a **mediastinoscopy**, a wand-like lighted camera (endoscope) and special instruments are passed through a small cut in the lower neck. The surgeon can see the tumor on a monitor and can cut off small samples for microscopic analysis. Mediastinoscopy is performed under general **anesthesia**. Alternatively, a needle biopsy will be taken in which a long needle is passed through the skin and into the tumor. Fine needle biopsy uses a thin needle and larger-core needle biopsy uses a wider needle. Needle biopsies may be performed in conjunction with CT imaging.

Patients who are having difficulty breathing may have a **bronchoscopy** performed to examine the wind pipe. An endoscope, in this case a bronchoscope, is inserted through the mouth and into the windpipe. The physician will look for tumors and may perform biopsies.

Treatment

Clinical staging

There is more than one type of staging system for thymoma; but the Masaoka system, a surgical staging system developed in 1981, is used most often. Thymoma is categorized into four stages (I, II, III, and IV), which may be further subdivided (A and B) based on the spread of cancerous tissue. The Masaoka staging system is as follows:

- Stage I. The thymoma lies completely within the thymus.
- Stage II. The thymoma has spread out of the thymus and invaded the outer layer of the lung (pleura) or nearby fatty tissue.
- Stage III. The thymoma has spread to other neighboring tissues of the upper chest, including the outer layer of the heart (pericardium), the lungs, or the heart's main blood vessels.
- Stage IVA. The thymoma has spread throughout the pericardium and/or the pleura.
- Stage IVB. The thymoma has spread to organs in other parts of the body.

In 1999, the World Health Organization (WHO) adopted a new classification system for thymic tumors. This system is a histologic classification, which means that it is based on the microscopic features of the cells that make up the tumor. The WHO classification system ranks thymomas into types A, AB, B1, B2, B3, and C, by increasing severity.

The treatment for thymoma depends on the stage of cancer and the patients overall health. Because thymomas are so rare, there are no defined treatment plans. Treatment options include surgery, **radiation therapy**, and/or **chemotherapy**. Surgical removal of the tumor is the preferred treatment. Surgery is often the only treatment required for stage I tumors. Treatment of thymoma often relieves the symptoms caused by paraneoplastic syndromes.

A treatment that is intended to aid the primary treatment is called adjuvant therapy. For instance, chemotherapy may be used along with surgery to treat thymoma. Stages II, III, and IV thymomas are often treated with surgery and some form of adjuvant therapy.

Surgery

Thymoma may be treated by surgically removing (resecting) the tumor and some of the nearby healthy tissue. Removal of the entire thymus gland is called a thymectomy. Surgery on the thymus is usually performed through the chest wall by splitting open the breast bone (sternum), a procedure called a median sternotomy. When complete removal of the tumor is impossible, the surgeon will remove as much of the tumor as possible (debulking surgery, subtotal resection). In these cases, if the tumor has spread, surgery may include removal of such other tissues as the pleura, pericardium, blood vessels of the heart, lung, and nerves.

Radiation therapy

Radiation therapy uses high-energy radiation from x rays and gamma rays to kill the cancer cells. Radiation given from a machine that is outside the body is called external radiation therapy. Radiation therapy is often used as adjuvant therapy following surgery to reduce the chance of cancer recurrence. Radiation may be used to kill cancer cells in cases in which the tumor was only partially removed. It may be used before surgery to shrink a large tumor. Radiation therapy is not very effective when used alone, although it may be used alone when the patient is too sick to withstand surgery.

The skin in the treated area may become red and dry and may take as long as a year to return to normal. Radiation to the chest may damage the lung, causing **shortness of breath** and other breathing problems. Also, the tube that goes between the mouth and stomach (esophagus) may be irritated by radiation, causing swallowing difficulties. **Fatigue**, upset stomach, **diarrhea**, and nausea are also common complaints of patients having radiation therapy. Most side effects go away two to three weeks after radiation therapy has ended.

Chemotherapy

Chemotherapy uses **anticancer drugs** to kill the cancer cells. The drugs are given by mouth (orally) or intravenously. They enter the bloodstream and can travel to all parts of the body. Chemotherapy may be given before surgery to shrink a tumor, which is called neoadjuvant therapy. Thymoma cells are very sensitive to anticancer drugs, especially cisplatin, doxorubicin, and ifosfamide. Generally, a combination of drugs is given because it is more effective than a single drug in treating cancer. **Corticosteroids** are also used to treat thymoma.

The side effects of chemotherapy are significant, and include stomach upset, **vomiting**, appetite loss, hair loss (**alopecia**), mouth sores, and fatigue. Women may experience vaginal sores, menstrual cycle changes, and **premature menopause**. There is also an increased chance of infections.

KEY TERMS

Adjuvant therapy—A treatment that is intended to aid the primary treatment. Adjuvant treatments for thymic cancer are radiation therapy and chemotherapy.

Invasive—A descriptive term for thymoma that has spread beyond the outer wall of the thymus.

Lymphocyte—A type of white blood cell that is found in the thymus.

Neoadjuvant therapy—Radiation therapy or chemotherapy used to shrink a tumor before surgical removal of the tumor.

Paraneoplastic syndrome—A set of symptoms that is associated with cancer but is not directly caused by the cancer.

Pleura—The outer covering of the lungs.

Alternatives

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques such as prayer, **biofeedback**, visualization, **meditation**, and **yoga**, have not shown any effect in reducing cancer; but they can reduce **stress** and lessen some of the side effects of cancer treatments. Gerson, macrobiotic, orthomolecular, and Cancell therapies are ineffective treatments for cancer.

Clinical studies of hydrazine sulfate found that it had no effect on cancer and even worsened the health and well-being of the study subjects. One clinical study of the drug amygdalin (Laetrile) found that it had no effect on cancer. Laetrile can be toxic and has caused deaths. Shark cartilage has been studied as a cancer treatment and is presently being studied by the FDA in clinical trials. Although the results are mixed, clinical studies suggest that melatonin may increase the survival time and quality of life for cancer patients.

Selenium, in safe doses, may delay the progression of cancer. Laboratory and animal studies suggest that curcumin, the active ingredient of turmeric, has anticancer activity. Maitake mushrooms may boost the immune system, according to laboratory and animal studies. The results of laboratory studies suggest that mistletoe has anticancer properties; however, clinical studies have not been conducted.

Prognosis

The five-year survival rates for thymomas are 96% for stage I, 86% for stage II, 69% for stage III, and 50% for stage IV. Thorough (radical) surgery is associated with a longer survival rate. Almost 15% of thymoma patients develop a second cancer.

Thymomas rarely spread (metastasize) outside of the chest cavity. Metastasis is usually limited to the pleura. Invasive thymomas are prone to recurrence, even 10–15 years following surgery. The recurrence rates are drastically reduced and the five-year survival rates are drastically increased in patients who receive adjuvant radiation therapy.

Prevention

Because there are no known risk factors for the development of thymoma, there are no preventive measures. However, there may be an association between thymic cancer and exposure of the chest to radiation.

Thyroid biopsy

Definition

The thyroid biopsy is a procedure in which a sample of thyroid tissue is withdrawn for laboratory examination. The sample can be withdrawn through a needle or a surgical incision may be made to obtain a piece of thyroid tissue.

Purpose

The test is generally performed when a lump or a nodule is detected in the thyroid. The test may also be ordered if the thyroid gland is enlarged and the cause is not apparent. The biopsy is usually a test for **thyroid cancer**.

Description

The thyroid is a butterfly–shaped gland located at the base of the neck. It produces thyroxine, a hormone that plays a very crucial role in regulating the metabolism of the body and controlling several vital functions, such as the heart beat, blood pressure, and body temperature. The thyroid also regulates childhood growth and development.

A thyroid biopsy is usually ordered when a painless lump or a nodule is detected, either by the patient or by a doctor during a routine **physical examination**. A biopsy is the only test that can accurately determine whether the lump is non–cancerous (benign) or cancerous (malignant). The biopsy can be performed in several ways.

Fine needle aspiration (FNA) can be done in the doctor's office. An anesthetic is not usually given. The patient will be asked to lie on his or her back. A pillow will be placed under the shoulders and the neck will be extended. The biopsy site will be cleansed with a sterile antiseptic solution. A thin needle will be inserted into the thyroid, and a sample of thyroid cells and some fluid will be collected. The needle will be quickly withdrawn. Pressure will be applied at the biopsy site to stop the bleeding and a bandage may be used to cover the area. The test takes 3–5 minutes.

For large needle biopsy, a mild sedative may be given an hour before the procedure, to relax the patient. The patient will be asked to lie on his or her back, with the head tipped back and the neck extended. The biopsy site will be thoroughly cleansed and the physician will inject a local anesthetic. A small incision (about 1 in. [2.54 cm]) will be made in the skin. The biopsy needle will be inserted through the incision into the thyroid. A sample of tissue will be removed and the needle withdrawn. Pressure is applied at the biopsy site to stem the bleeding and a bandage applied. This test takes 5–10 minutes.

The open incisional biopsy is done in an operating room by a surgeon. The patient is given a general anesthetic. A sedative is given an hour before the procedure to relax the patient. An intravenous line is placed in the arm for infusion of fluids or drugs. An endotracheal tube is inserted through the mouth into the lungs for administering anesthetic gases. After the patient is anesthetized, a small incision is made in the neck. Either the whole thyroid or a part of it is removed. If only a portion is being removed, the surgeon may send a small piece of remaining tissue to the laboratory for immediate testing while the patient is still on the operating table. If the pathologist's report comes back stating that cancer is present in the remaining tissue, the entire thyroid is removed. The incision is closed with stitches. The whole procedure may take about an hour.

Preparation

The doctor should be informed of any **allergies** to medications and provided a list of every medication the patient is taking. The doctor should be told if the patient is pregnant.

The patient will be asked to sign the necessary consent forms. If a needle biopsy is done, no special preparation is needed. If a large needle biopsy is being done, the doctor may order some tests to determine the clotting ability of the blood. In addition, the patient may be instructed not to eat or drink for at least four hours prior to the procedure to minimize the risk for **nausea and vomiting**. The patient will also be asked to urinate immediately before starting preparation for the procedure. If an open incisional biopsy is being done, a general anesthetic is required and the patient will be asked to refrain from eating or drinking anything 8–12 hours before the test.

Aftercare

The needle used in fine needle aspiration is so thin, the whole procedure feels like a quick injection. There is no **pain** or tenderness at the site after the test. In large needle biopsy, a stinging needle prick may be felt when the local anesthetic is injected. The site may be sore for a few hours and tender for a day or two after the test.

In the open incisional biopsy, the patient will feel nothing during the procedure, because of the effects of the anesthetic and the sedative. However, the anesthetic may cause the patient to feel drowsy for several hours after the procedure. The anesthetic may also cause the patient to experience some **fatigue**, and general aches and pains for a day or two after the procedure. The endotracheal tube may make the throat feel mildly sore. Sutures may be necessary to close the incisional biopsy site. Some **home care** of the sutures may be required. Discharge instructions will typically be provided if suture care is required. If there is swelling at the biopsy site or if the patient develops a **fever**, the doctor should be notified immediately.

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Endotracheal tube—A hollow tube that is inserted into the windpipe (trachea), leading to the lungs.

Pathologist—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

Risks

No risks are associated with fine needle aspiration. Large needle biopsy may cause bleeding into the thyroid gland. There is a small risk that the anesthetic used in open surgical biopsy may cause a life–threatening reaction.

A patient with a bleeding disorder should not have a biopsy unless the bleeding problem can be corrected by a **transfusion** of the cells that cause blood to clot (platelets).

Results

The normal appearance and architecture of the thyroid cells indicate that no cancer cells are present in the thyroid tissue.

Any abnormalities of the thyroid tissue cells may indicate cancer, benign tumors, or some other thyroid disease. If cancer is suspected, the pathologist may do some more testing to identify the extent of the cancer, so that it can be treated appropriately.

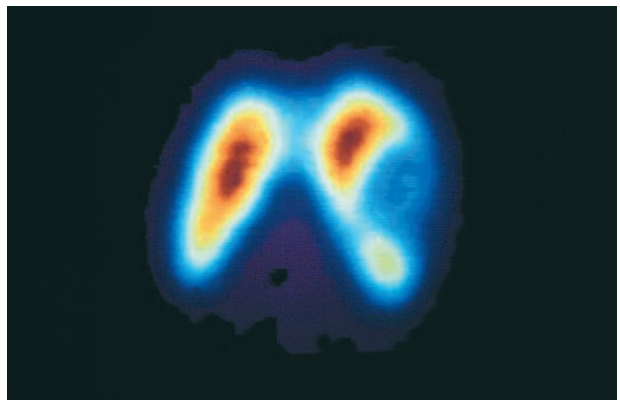
Thyroid cancer

Definition

Thyroid cancer is a disease in which the cells of the thyroid gland become abnormal, grow uncontrollably and form a mass of cells called a tumor.



A gamma scan of the human thyroid gland revealing cancer. *(Custom Medical Stock Photo, Inc.)*

Demographics

Diseases of the thyroid gland affect millions of Americans. The most common diseases of the thyroid are **hyperthyroidism** (Grave's disease) and **hypothyroidism**, an overactive or an underactive gland, respectively. Sometimes lumps or masses may develop in the thyroid. Although most (95%) of these lumps or nodules are non-cancerous (benign), all thyroid lumps should be taken seriously.

Thyroid cancer is one of the most treatable forms of cancer with the five year overall survival rate for all stages and all tumor types at 97%. The American Cancer Society estimates that in 2009, approximately 37,200 new cases of thyroid cancer were diagnosed in the United States and less than 2,000 individuals died from the disease.

Women are three times more likely to develop thyroid cancer than men. Unlike many cancers, thyroid cancers are most often diagnosed in younger people, with almost two-thirds of cases diagnosed in individuals between the ages of 20 and 55. Caucasians are affected more often than African Americans.

The incidence of thyroid cancer has increased slightly in recent years although this increase is thought to be primarily related to increased sophistication of detection capabilities. The death rate from thyroid cancer has remained stable for several years.

Description

The thyroid is a hormone-producing, butterfly-shaped gland located in the neck at the base of the throat. It has two lobes, the left and the right. The thyroid uses iodine, a mineral found in some foods, to make several of its hormones. **Thyroid hormones** regulate essential body processes such as heart rate, blood

Follicular	10–15% of thyroid cancers Found in hormone-producing cells	90% of patients will live for 15 years or longer after diagnosis
Medullary	5–7% of thyroid cancers Found in calcitonin-producing cells Difficult to control as it often spreads to other parts of the body	80% of patients will live for at least 10 years after surgery

pressure, body temperature, metabolism, and affect the nervous system, muscles and other organs. These hormones play an important role in regulating childhood growth and development.

Types of thyroid cancer

Thyroid cancer is grouped into types based on how cells appear under a microscope. Differentiated thyroid cancers include papillary carcinoma (the most common type of thyroid tumor) and follicular carcinoma. Hurthle cell thyroid cancer is a subtype of follicular carcinoma. Other less commonly occurring types of thyroid cancers include medullary thyroid carcinomas, anaplastic thyroid cancers, and thyroid lymphomas. They grow at different rates and can spread to other parts of the body if left untreated. The two most common types of thyroid cancer are papillary carcinoma and follicular carcinoma.

PAPILLARY. The papillary type (60–80% of all thyroid cancers) is a slow-growing cancer that develops in the hormone-producing cells containing iodine.

FOLLICULAR. The follicular type (30–50% of thyroid cancers) also develops in the hormone-producing cells.

MEDULLARY. The medullary type (5–7% of all thyroid cancers) develops in the parafollicular cells (known as the C cells) that produce calcitonin, a hormone that does not contain iodine.

ANAPLASTIC. The anaplastic type of thyroid cancer (2% of all thyroid cancers), is the fastest growing, most aggressive type.

Risk factors

Risk factors associated with the development of thyroid cancer include:

- gender: thyroid cancers are diagnosed in women three times as often as in men
- age: most cases of thyroid cancer are diagnosed between the ages of 20 and 55 years
- diet: consumption of diets low in iodine have been linked to the development of papillary and follicular thyroid cancers
- radiation exposure: radiation exposure, particularly exposure in childhood, places individuals at higher risk for the development of thyroid cancer
- heredity: about 20% of cases of medullary thyroid cancer are related to an inherited genetic abnormality; individuals with other inherited diseases such as Gardner syndrome, Cowden disease and familial adenomatous polyposis (FAP), appear to be at increased risk for the development of certain types of thyroid cancer

Causes and symptoms

The exact cause of thyroid cancer is not known but, some risk factors have been identified. Radiation was used in the 1950s and 1960s to treat **acne** and to reduce swelling in infections of the tonsils, adenoids

WWW.BOOKBAZ.IR

and lymph nodes. It has been proven that this exposure is a risk factor for thyroid cancer. In some areas of the world, **diets** are low in iodine. Papillary and follicular cancers occur more frequently in these areas. Iodine deficiency is not a large problem in the United States because iodine is added to table salt and other foods. Approximately 7% of thyroid cancers are caused by the alteration (mutation) of a gene called the RET oncogene, which can be inherited.

Symptoms of thyroid cancer are rare. Many thyroid tumors present as a painless lump in the neck. Some tumors are found during routine health-related checkups. The following are signs and symptoms of thyroid nodules.

- A lump or nodule that can be felt in the neck is the most frequent sign of thyroid cancer.
- The lymph nodes in the neck may be swollen and the voice may become hoarse because the tumor presses on the nerves leading to the voice box.
- Some patients experience a tight or full feeling in the neck and have difficulty breathing or swallowing.

Diagnosis

Examination

A physician will carefully examine the neck and lymph nodes in the area if a thyroid tumor is suspected or if a patient complains of anterior neck **pain**, swelling, hoarseness or if a suspicious lump is present.

Tests

Physicians use several tests to confirm the suspicion of thyroid cancer, to identify the size and location of the lump and to determine whether the lump is noncancerous (benign) or cancerous (malignant).

A blood test called the thyroid stimulating hormone (TSH) test checks thyroid function.

The calcitonin test may be ordered to evaluate calcitonin levels in blood. Calcitonin is a hormone produced by the C cells (parafollicular cells) of the thyroid gland. The hormone is produced in excess when the parafollicular cells of the thyroid become cancerous. Results of this test are used to confirm the diagnosis of medullary thyroid. Another blood test, the carcinoembryonic antigen (CEA), test may be done if medullary thyroid cancer is suspected. CEA levels are usually high in patients with this type of thyroid cancer.

Computed tomography (CT) scan or ultrasonography (an **ultrasound** scan) are imaging tests used to produce a picture of the thyroid. A radiologist usually interprets the results of these tests within 24 hours. In ultrasonography, high-frequency sound waves are bounced off the thyroid. The pattern of echoes produced by these waves is converted into a computerized image on a television screen. This test can determine whether the lumps found in the thyroid are benign fluid-filled cysts or solid malignant tumors.

A nuclear medicine radioiodine scan is used to identify abnormal areas in the thyroid. For this test, the patient is given a very small amount of radioactive iodine that can either be swallowed or injected. Since the thyroid is the only gland in the body that absorbs iodine, the radioactive iodine accumulates there. An x-ray image is taken or an instrument called a scanner is used to identify areas in the thyroid that do not absorb iodine normally. These abnormal spots are called cold spots and further tests are performed to check whether the cold spots are benign or malignant tumors. If a significant amount of radioactive iodine is concentrated in the nodule, then it is termed "hot" and is usually benign. A radiologist interprets the results within a day.

An octreotide scan may be ordered to detect the spread of medullary thyroid cancer.

Other tests that may be ordered to assist in the diagnosis of thyroid cancer include **magnetic resonance imaging** (MRI) and **positron emission tomography** (PET) scans.

Procedures

The most accurate diagnostic tool for thyroid cancer is a biopsy. In this process, a sample of thyroid tissue is obtained and examined under a microscope by a pathologist. This usually takes a day. The tissue sample can be obtained either by drawing out a sample of tissue through a needle (such as a fine needle aspirate biopsy) or by surgical removal of the nodule (surgical biopsy). A needle biopsy takes a few minutes and can be done by a trained physician, usually a radiologist. The surgical biopsy is done by a surgeon under general **anesthesia** with the help of an anesthesiologist and takes a few hours. If thyroid cancer is diagnosed, further tests may be done to determine the stage of the disease and help doctors plan appropriate treatment.

Staging

The aggressiveness of each type of thyroid cancer is different. Cancer staging considers the size of the tumor, whether it has grown into surrounding lymph nodes and whether it has spread to distant parts of the body (metastasized). Age and general health status are also taken into account. The American Joint Commission on Cancer (AJCC) staging is summarized for each thyroid cancer type as follows:

PAPILLARY AND FOLLICULAR. In patients younger than 45 years:

- Stage I: Patients without evidence of cancer beyond the thyroid.
- Stage II: Patients with spread of cancer outside the thyroid gland to one or more distant sites.

In patients over 45:

- Stage I: Tumors are smaller than 2 cm (0.3 in.).
- Stage II: Tumors are 2–4 cm (0.3–0.6 in.) across but have not spread to adjacent lymph nodes or distant sites.
- Stage III: Tumors have spread locally to nearby lymph nodes or are larger than 4 cm (0.6 in.) and have grown slightly outside of the thyroid but not into lymph nodes or distant sites.
- Stage IV: Tumors have spread outside the thyroid area (distant metastases).

In the case of Stage IV cancer, the places to which thyroid cancer often metastasizes are the lungs and bone.

MEDULLARY. The stages of medullary thyroid carcinomas for individuals at any age are the same as for papillary or follicular thyroid cancer in people over age 45.

ANAPLASTIC. All cases of anaplastic thyroid cancer are considered Stage IV because this type of cancer is extremely aggressive.

Treatment

Papillary thyroid cancer can be treated successfully. Follicular thyroid cancer also has a good cure rate, but may be difficult to control if the cancer invades blood vessels or spreads to nearby structures in the neck. Medullary thyroid cancers are more difficult to control because they often spread to other parts of the body. Anaplastic thyroid cancer is the fastest growing and tends to respond poorly to all treatments.

Like most cancers, cancer of the thyroid is best treated when it is found early by a primary physician. Treatment depends on the type of cancer and its stage. Several treatment modalities are used in the treatment of thyroid cancer including surgical removal of the tumor, external beam **radiation therapy**, thyroid hormone therapy, **chemotherapy** and radioactive hormone therapy. Using a combination of these therapies typically leads to optimal results.

Surgery

Surgical removal is the usual treatment if the cancer has not spread to distant parts of the body. It is the primary treatment for early stage papillary, follicular, and medullary thyroid cancers. The surgeon may remove the side or lobe of the thyroid where the cancer is found (**lobectomy**) or all of it (total **thyroidectomy**). If the adjoining lymph nodes are affected, they may also be removed during surgery.

Radiation/radioactive iodine therapy

For papillary and follicular thyroid cancers, radioactive iodine may be used in addition to surgery. In this treatment, the patient is asked to swallow a drink containing radioactive iodine. Because the thyroid cells take up iodine, the radioactive iodine collects in any thyroid tissue remaining in the body and kills the cancer cells. External beam radiation may be used if the radioactive iodine is unsuccessful.

For medullary cancers, radioactive iodine is not used. External beam radiation may be used as a palliative therapy. (A palliative therapy is one intended to make the patient more comfortable, not to cure the cancer.)

Hormone therapy

Removal of the thyroid gland causes levels of thyroid hormones to decrease. The pituitary gland then produces TSH, which normally stimulates the thyroid gland to make thyroid hormone. TSH stimulates thyroid cells to grow, and most likely promotes thyroid cancer growth. Hormone therapy uses hormones after surgery to stop this growth and the formation of new cancerous thyroid cells. To prevent cancerous growth, the natural hormones produced by the thyroid are taken in the form of a pill. This maintains normal hormone levels and inhibits the pituitary gland from making TSH. If the cancer has spread to other parts of the body and surgery is not possible, hormone treatment is aimed at killing or slowing the growth of cancer cells throughout the body.

Chemotherapy

For advanced thyroid cancers for which surgery was not an option or that have not responded well to other treatments, chemotherapy may be used. There is no standard chemotherapeutic regimen for advanced papillary, follicular, and anaplastic thyroid cancers. Clinical studies are ongoing for patients with these cancers. Anaplastic thyroid cancer may show an increased local response to the chemotherapeutic agent, doxorubicin, which is used as a radiation sensitizer in combination with hyperfractionated radiation therapy. Paclitaxel may provide some palliative benefit. Patients with anaplastic thyroid cancer may be eligible for ongoing clinical trials.

WWW.BOOKBAZ.IR

Prognosis

As of 2014, the approximate ten year overall survival rates for individuals with thyroid cancer by type of cancer are:

- Papillary–93%
- Follicular - 85%
- Medullary–75%
- Anaplastic/undifferentiated carcinomas–14%

Prevention

It is not possible to prevent this disease completely because most people with thyroid cancer have no known risk factor. The risk for radiation-related thyroid cancer can be reduced by avoiding radiation to the neck when possible. Inherited cases of medullary thyroid cancer can be prevented. If a family member has had this disease, other family members can be tested and treated early. Carriers of the RET mutation may want to consider a prophylactic thyroidectomy at an early age. The National Cancer Institute recommends that every one or two years, a doctor examine anyone who has received radiation to the head and neck during childhood. The neck and thyroid should be carefully examined for any lumps or enlargement of nearby lymph nodes. Ultrasound may be used to screen for the disease in people at risk for thyroid cancer.

Thyroid function tests

Definition

Thyroid function tests are blood tests used to evaluate how effectively the thyroid gland is working. These tests include the thyroid-stimulating hormone test (TSH), the thyroxine test (T_4), the triiodothyronine test (T_3), the thyroxine-binding globulin test (TBG), the triiodothyronine resin uptake test (T_3RU), and the long-acting thyroid stimulator test (LATS).

Purpose

Thyroid function tests are used to:

- help diagnose an underactive thyroid (hypothyroidism) and an overactive thyroid (hyperthyroidism)
- evaluate thyroid gland activity
- monitor response to thyroid therapy

Description

Most doctors consider the sensitive thyroid-stimulating hormone (TSH) test to be the most accurate measure of thyroid activity. It is used to diagnose primary **hypothyroidism**, as well as to monitor the effects of exogenous thyroid replacement or suppression therapy. Because this test is so sensitive, abnormalities in thyroid function can be determined before a patient complains of symptoms.

TSH "tells" the thyroid gland to secrete the hormones thyroxine (T_4) and triiodothyronine (T_3). Before TSH tests were used, standard blood tests measured levels of T_4 and T_3 to determine if the thyroid gland was working properly. The triiodothyronine (T_3) test measures the amount of this hormone in the blood. T_3 is normally present in very small amounts but has a significant impact on metabolism and is the active component of **thyroid hormones**.

The thyroxine-binding globulin (TBG) test measures blood levels of this substance, which is manufactured in the liver. TBG binds to T_3 and T_4, prevents the kidneys from flushing the hormones from the blood, and releases them when and where they are needed to regulate body functions.

The triiodothyronine resin uptake (T_3RU) test measures blood T_4 levels. Laboratory analysis of this test takes several days, and it is used less often than tests whose results are available more quickly.

The long-acting thyroid stimulator (LATS) test shows whether blood contains long-acting thyroid stimulator. Not normally present in blood, LATS causes the thyroid to produce and secrete abnormally high amounts of hormones. The LATS test is useful in diagnosing Graves' disease.

It takes only minutes for a nurse or medical technician to collect the blood needed for these blood tests. A needle is inserted into a vein, usually in the forearm, and a small amount of blood is collected and sent to a laboratory for testing. The patient will usually feel minor discomfort from the "stick" of the needle.

Precautions

Thyroid treatment must be stopped one month before blood is drawn for a thyroxine (T_4) test.

Steroids, propranolol (Inderal), cholestyramine (Questran), and other medications that may influence thyroid activity are usually stopped before a triiodothyronine (T_3) test.

Estrogens, anabolic steroids, phenytoin (Dilantin), and thyroid medications may be discontinued prior to a thyroxine-binding globulin (TBG) test. The laboratory analyzing the blood sample must be told if the patient cannot stop taking any of these medications. Some patients will be told to take these medications as usual so that the doctor can determine how they affect thyroxine-binding globulin.

Patients are asked not to take estrogens, androgens, phenytoin, salicylates (e.g., **aspirin**), and thyroid medications before having a triiodothyronine resin uptake (T_3RU) test.

Prior to taking a long-acting thyroid stimulant (LATS) test, the patient will probably be told to stop taking all drugs that could affect test results.

Preparation

There is no need to make any changes in diet or activities. The patient may be asked to stop taking certain medications until after the test is performed.

Aftercare

Warm compresses can be used to relieve swelling or discomfort at the site of the puncture. With a doctor's approval, the patient may start taking medications stopped before the test.

Results

Not all laboratories measure or record thyroid hormone levels the same way. Each laboratory will provide a range of values for each test.

Normal

TSH. Normal TSH levels for adults are 0.5–5.0 mU/L.

T_4. Normal T_4 levels for adults are 4.5–12.6 ug/dL, according to the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). Results may vary slightly based on the laboratory methods used. Levels are typically higher at birth and then gradually decrease to the normal range.

Normal T_4 levels do not necessarily indicate normal thyroid function. T_4 levels can register within normal ranges in a patient who:

- is pregnant
- has recently had contrast x rays
- has nephrosis (kidney disease) or cirrhosis (liver disease)

T_3. Normal T_3 levels are:

- 90–170 ng/dL at birth
- 115–190 ng/dL at 6–12 years
- 110–230 ng/dL in adulthood

TBG. Normal TBG levels are:

- 1.5–3.4 mg/dL or 15–34 mg/L in adults
- 2.9–5.4 mg/dL or 29–54 mg/L in children

T_3RU. Between 25% and 35% of T_3 should bind to or be absorbed by the resin added to the blood sample. The test indirectly measures the amount of thyroid binding globulin (TBG) and thyroid-binding prealbumin (TBPA) in the blood.

LATS

Long-acting thyroid stimulator is found in the blood of only 5% of healthy people.

Abnormal results

T_4. Elevated T_4 levels can be caused by:

- acute thyroiditis
- birth control pills
- clofibrate (Altromed-S), a medication used to lower cholesterol and triglyceride levels
- contrast x rays using iodine
- estrogen therapy
- heparin, a medication used to prevent blood clots
- heroin
- hyperthyroidism
- pregnancy
- thyrotoxicosis
- toxic thyroid adenoma

Cirrhosis and severe non-thyroid disease can raise T_4 levels slightly.

Reduced T_4 levels can be caused by:

- anabolic steroids
- androgens
- antithyroid drugs
- cretinism
- hypothyroidism

WWW.BOOKBAZ.IR

- kidney failure
- lithium (Lithane, Lithonate)
- myxedema
- phenytoin
- propranolol

T_3. Although T_3 levels usually rise and fall when T_4 levels do, T_3 toxicosis causes T_3 levels to rise while T_4 levels remain normal. T_3 toxicosis is a complication of:

- Graves' disease
- toxic adenoma
- toxic nodular goiter

T_3 levels normally rise when a woman is pregnant or using birth-control pills. Elevated T_3 levels can also occur in patients who use estrogen, **methadone**, or who have:

- certain genetic disorders that do not involve thyroid malfunction
- hyperthyroidism
- thyroiditis
- T_3 thyrotoxicosis
- toxic adenoma

Low T_3 levels may be a symptom of:

- acute or chronic illness
- hypothyroidism
- kidney or liver disease
- starvation

Decreased T_3 levels can also be caused by using:

- anabolic steroids
- androgens
- phenytoin
- propranolol
- reserpine (Serpasil)
- salicylates in high doses

TBG. TBG levels, normally high during **pregnancy**, are also high in newborns. Elevated TBG levels can also be symptoms of:

- acute hepatitis, a disease characterized by inflammation of the liver
- acute intermittent porphyria, an inherited disease affecting the liver and bone marrow
- hypothyroidism
- inherited thyroid hormone abnormality

TBG levels can also become high by using:

- anabolic steroids
- birth control pills
- anti-thyroid agents

LATS

Long-acting thyroid stimulator, not usually found in blood, is present in the blood of 80% of patients with Graves' disease. It is a symptom of this disease whether or not symptoms of hyperthyroidism are detected.

Thyroid gland removal *see* **Thyroidectomy**

Thyroid hormones

Definition

Thyroid hormones are artificially made hormones that make up for a lack of natural hormones produced by the thyroid gland.

Purpose

The thyroid gland, a butterfly-shaped structure in the lower part of the neck, normally produces a hormone called thyroxine. This hormone controls the rate of metabolism – all the physical and chemical processes that occur in cells to allow growth and maintain body functions. When the thyroid gland does not produce enough thyroxine, body processes slow down. People with underactive thyroid glands feel unusually tired and may gain weight even though they eat less. They may also have trouble staying warm and may have other symptoms, such as dry skin, dry hair, and a puffy face. By making up for the lack of natural

WWW.BOOKBAZ.IR

thyroxine and bringing the rate of metabolism back to normal, artificially made thyroid hormone improves these symptoms.

Thyroid hormones also may be used to treat **goiter** (enlarged thyroid gland) and certain types of **thyroid cancer**.

Description

Thyroid hormones, also called thyroid drugs, are available only with a physician's prescription. They are sold in tablet form. A commonly used thyroid hormone is levothyroxine (Synthroid, Levoxyl, Levothroid).

Recommended dosage

For adults and teenagers, the usual starting dose of levothyroxine tablets is 0.0125 mg (12.5 micrograms) to 0.05 mg (50 micrograms) per day. The physician who prescribes the medicine may gradually increase the dose over time.

For children, the dose depends on body weight and must be determined by a physician.

Taking thyroid hormones exactly as directed is very important. The physician who prescribes the medicine will figure out exactly how much of the medicine a patient needs. Taking too much or too little can make the thyroid gland overactive or underactive.

This medicine should be taken at the same time every day.

Precautions

People who take thyroid hormones because their thyroid glands do not produce enough natural hormone may need to take the medicine for the rest of their lives. Seeing a physician regularly while taking this medicine is important. The physician will make sure that the medicine is working and that the dosage is correct.

In patients with certain kinds of **heart disease**, this medicine may cause chest pains and **shortness of breath** during **exercise**. People who have this problem should be careful not to exert themselves too much.

Anyone who is taking thyroid hormones should be sure to tell the healthcare professional in charge before having any surgical or dental procedures or receiving emergency treatment.

This medicine is safe to take during **pregnancy**, but the dosage may need to be changed. Women who are pregnant should check with their physicians to make sure they are taking the proper dosage.

Anyone who has had unusual reactions to thyroid hormones in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

Before using thyroid hormones, people with any of these medical problems should make sure their physicians are aware of their conditions:

- heart disease
- high blood pressure
- hardening of the arteries
- diabetes
- history of overactive thyroid
- underactive adrenal gland
- underactive pituitary gland

Side effects

This medicine usually does not cause side effects if the dosage is right. Certain symptoms may be signs that the dose needs to be changed. Check with a physician if any of these symptoms occur:

- headache
- fever
- diarrhea
- vomiting
- changes in appetite
- weight loss
- changes in menstrual period
- tremors of the hands
- leg cramps
- increased sensitivity to heat
- sweating
- irritability
- nervousness
- sleep problems

Other side effects are possible. Anyone who has unusual symptoms while taking thyroid hormones should get in touch with his or her physician.

Interactions

Thyroid hormones may interact with other medicines. This may increase or decrease the effects of the thyroid medicine and may interfere with treatment. Anyone who takes thyroid hormones should not take any other prescription or nonprescription (over-the-counter) medicines without the approval of his or her physician. Among the drugs that may interact with thyroid hormones are:

KEY TERMS

Adrenal glands—A pair of glands located next to the kidneys. The adrenal glands produce hormones that control many body functions.

Hormone—A chemical that is produced in one part of the body and then travels through the bloodstream to another part of the body where it has its effect.

Pituitary gland—A pea-sized gland at the base of the brain that produces many hormones that affect growth and body functions.

- Medicine for colds, hay fever, and other allergies
- Medicine for asthma and other breathing problems
- Medicine for diabetes
- Blood thinners
- Amphetamines
- Diet pills (appetite suppressants)
- Cholesterol-lowering drugs such as cholestyramine (Questran) and colestipol (Colestid).

Thyroid nuclear medicine scan

Definition

A thyroid nuclear medicine scan is a diagnostic procedure to evaluate the thyroid gland, which is located in the front of the neck and controls the body's metabolism. A radioactive substance that concentrates in the thyroid is taken orally or injected into a vein (intravenously), or both. A special camera is used to take an image of the distribution of the radioactive substance in and around the thyroid gland. This is interpreted to evaluate thyroid function and to diagnose abnormalities.

Purpose

A thyroid scan may be ordered by a physician when the gland becomes abnormally large, especially if the enlargement is greater on one side, or when hard lumps (nodules) are felt. The scan can be helpful in determining whether the enlargement is caused by a diffuse increase in the total amount of thyroid tissue or by a nodule or nodules.

When other laboratory studies show an overactive thyroid (**hyperthyroidism**) or an underactive thyroid (**hypothyroidism**), a radioactive iodine uptake scan is often used to confirm the diagnosis. It is frequently done along with a thyroid scan.

Precautions

Women who are pregnant should not have this test.

Description

This test is performed in a **radiology** facility, either in an outpatient x ray center or a hospital department. Most often, the patient is given the radioactive substance in the form of a tasteless liquid or capsule. It may be injected into a vein (intravenously) in some instances. Images will be taken at a specified amount of time after this, depending on the radioisotope used. Most often, scanning is done 24 hours later, if the radioisotope is given orally. If it is given intravenously, the scan is performed approximately 20 minutes later.

For a thyroid scan, the patient is positioned lying down on his or her back, with the head tilted back. The radionuclide scanner, also called a gamma camera, is positioned above the thyroid area as it scans. This takes 30-60 minutes.

The uptake study may be done with the patient sitting upright in a chair or lying down. The procedure is otherwise the same as described for the thyroid scan. It takes approximately 15 minutes. There is no discomfort involved with either study.

A thyroid scan may also be referred to as a thyroid scintiscan. The name of the radioactive substance used may be incorporated and the study called a technetium thyroid scan or an iodine thyroid scan. The radioactive iodine uptake scan may be called by its initials, an RAIU test, or an iodine uptake test.

Preparation

Certain medications can interfere with iodine uptake. These include certain **cough** medicines, some **oral contraceptives**, and thyroid medications. The patient is usually instructed to stop taking these

WWW.BOOKBAZ.IR

medicines for a period of time before the test. This period may range from several days up to three to four weeks, depending on the amount of time the medicine takes to clear from the body.

Other nuclear medicine scans and x-ray studies using contrast material performed within the past 60 days may affect this test. Patients should tell their doctors if they have had either of these types of studies before the thyroid scan is begun, to avoid inaccurate results.

Some institutions prefer that the patient have nothing to eat or drink after midnight on the day before the radioactive liquid or capsule is to be taken. A normal diet can usually be resumed two hours after the radioisotope is taken. Dentures, jewelry, and other metallic objects must be removed before the scanning is performed. No other physical preparation is needed.

The patient should understand that there is no danger of radiation exposure to themselves or others. Only very small amounts of radioisotope are used. The total amount of radiation absorbed is often less than the dose received from ordinary x rays. The scanner or camera does not emit any radiation, but detects and records it from the patient.

Aftercare

No **isolation** or special precautions are needed after a thyroid scan. The patient should check with his or her physician about restarting any medications that were stopped before the scan.

Risks

There are no risks with this procedure.

Results

A normal scan will show a thyroid of normal size, shape, and position. The amount of radionuclide uptake by the thyroid will be normal according to established laboratory figures. There will be no areas where radionuclide uptake is increased or decreased.

Abnormal results

An area of increased radionuclide uptake may be called a hot nodule or "hot spot." This means that a benign growth is overactive. Despite the name, hot nodules are unlikely to be caused by cancer.

An area of decreased radionuclide uptake may be called a cold nodule or "cold spot." This indicates that this area of the thyroid gland is underactive. A variety of conditions, including cysts, nonfunctioning benign growths, localized inflammation, or cancer may produce a cold spot.

A thyroid nuclear medicine scan is rarely sufficient to establish a clear diagnosis. Frequently, the information revealed will need to be combined with data from other studies to determine the problem.

KEY TERMS

Radioisotope—A radioactive or radiation-emitting form of an element.

Radionuclide—A substance that emits radiation as it disintegrates.

Thyroid ultrasound

Definition

Thyroid **ultrasound** is an imaging technique used for diagnosing suspected thyroid disease. It uses harmless, high-frequency sound waves to form an image. The sound waves are reflected by thyroid tissue to form a picture of internal structures. It is not invasive and involves no radiation.

Purpose

The thyroid gland is an organ located in front of the neck. It plays an important role in controlling the body's metabolism. Most thyroid ultrasounds are performed to evaluate a small lump (nodule) in the thyroid found during a **physical examination** or found by a radionuclide study (thyroid scan). The ultrasound can establish if the nodule is a cyst, which is an abnormal lump that contains fluid, or a solid mass. Cysts are almost always noncancerous (benign), although in some cases the fluid may be taken out for additional testing.

If there are several masses or nodules, this indicates the presence of enlargement of the thyroid gland (**goiter**). If there is only one mass, it may be cancerous and needs further evaluation. Specialized thyroid ultrasounds, such as color Doppler flow studies, can add valuable information. By showing an image of the blood circulation in the gland, this study can assess some ambiguous masses in greater detail, to further refine diagnosis. In some cases, a needle will be inserted to remove some tissue from the mass for evaluation in a laboratory (needle biopsy). Ultrasound is used during this procedure to help the physician guide the needle to the mass that needs to be evaluated.

Thyroid ultrasound can measure the size of the thyroid with great precision. Ultrasound studies may be done periodically to assess the response of the thyroid gland to medical therapy. An enlarged gland or a benign nodule should decrease in size when appropriate thyroid medication is taken.

Patients who have received therapeutic radiation to the head or neck may be monitored at regular intervals using thyroid ultrasound. The radiation puts these patients at higher risk for developing **thyroid cancer** or other abnormalities. In the early stages, these conditions may not cause symptoms or be apparent during a physical examination. They can, however, be detected by ultrasound.

Certain invasive medical procedures may be performed under ultrasound guidance. This is because ultrasound allows the physician to observe a needle as it enters body tissue below the skin. This is useful to direct the removal of fluid from a cyst (aspiration) or needle biopsy. Medications to treat recurrent cysts may be administered directly to the area using ultrasound guidance.

Precautions

Thyroid ultrasound is safe for people of all ages. It is the preferred procedure to evaluate suspected disease in pregnant women because no radiation is involved.

Description

The study may be done in an outpatient facility or in a hospital department. The patient lies on his or her back. A pillow or rolled towel is placed under the shoulders and upper back, allowing the head to tilt back (hyperextend). A gel that enhances sound transmission is spread over the thyroid area. The technologist then gently places a transducer, an instrument about the size of an electric shaver, against the skin. It is moved over the thyroid area. The images from reflected sound waves appear on a monitor screen. There is no discomfort involved with this study. The examination takes 15–30 minutes.

Preparation

Some facilities recommend limiting food and drink for one hour before the study to prevent discomfort. No other preparation is needed.

Aftercare

No special restrictions or procedures are needed after a thyroid ultrasound.

Risks

There are no risks with this procedure.

Results

A normal study would reveal a thyroid gland of normal size, shape, position, and uniform texture.

Abnormal results

A thyroid ultrasound may reveal cysts, solid masses that may or may not be cancerous, or an enlarged thyroid gland (goiter). In many cases, the ultrasound can establish a diagnosis. Sometimes the information revealed will need to be combined with data from other studies to determine the problem.

Thyroidectomy

Definition

Thyroidectomy is a surgical procedure in which all or part of the thyroid gland is removed. The thyroid gland is located in the forward (anterior) part of the neck just under the skin and in front of the Adam's apple. The thyroid is one of the body's endocrine glands, which means that it secretes its products inside

WWW.BOOKBAZ.IR

the body, into the blood or lymph. The thyroid produces several hormones that have two primary functions: they increase the synthesis of proteins in most of the body's tissues, and they raise the level of the body's oxygen consumption.

Purpose

All or part of the thyroid gland may be removed to correct a variety of abnormalities. If a person has a **goiter**, which is an enlargement of the thyroid gland that causes swelling in the front of the neck, the swollen gland may cause difficulties with swallowing or breathing. **Hyperthyroidism** (overactivity of the thyroid gland) produces hypermetabolism, a condition in which the body uses abnormal amounts of oxygen, nutrients, and other materials. A thyroidectomy may be performed if the hypermetabolism cannot be adequately controlled by medication, or if the condition occurs in a child or pregnant woman. Both cancerous and noncancerous tumors (frequently called nodules) may develop in the thyroid gland. These growths must be removed, in addition to some or all of the gland itself.

Demographics

According to the American Thyroid Association, about 20 million people in the United States have a type of thyroid disorder, with up to 60% being undiagnosed.

Many people with abnormal levels of thyroid hormone do not have any disease symptoms. Females are somewhat more likely than males to require a thyroidectomy.

Description

Thyroidectomies are usually performed by surgeons with specialized training in otolaryngology, head and neck surgery. Occasionally, a general surgeon will perform a thyroidectomy. The procedure is performed in a hospital under general anesthesia.

A thyroidectomy begins with general **anesthesia** administered by an anesthesiologist. The anesthesiologist injects drugs into the patient's veins and then places an airway tube in the windpipe to ventilate (provide air for) the person during the operation. After the patient has been anesthetized, the surgeon makes an incision in the front of the neck at the level where a tight-fitting necklace would rest. The surgeon locates and takes care not to injure the parathyroid glands and the recurrent laryngeal nerves, while freeing the thyroid gland from these surrounding structures. The next step is clamping off the blood supply to the portion of the thyroid gland that is to be removed. Next, the surgeon removes all or part of the gland. If cancer has been diagnosed, all or most of the gland is removed. If other diseases or nodules are present, the surgeon may remove only part of the gland. The total amount of glandular tissue removed depends on the condition being treated. The surgeon may place a drain, which is a soft plastic tube that allows tissue fluids to flow out of an area, before closing the incision. The incision is closed with either sutures (stitches) or metal clips. A dressing is placed over the incision and the drain, if one has been placed.

People generally stay in the hospital one to four days after a thyroidectomy.

KEY TERMS

Endocrine—A type of organ or gland that secretes hormones or other products inside the body, into the bloodstream or the lymphatic system. The thyroid is an endocrine gland.

Endocrinologist—A physician who specializes in treating persons with diseases of the thyroid, parathyroid, adrenal glands, and the pancreas.

Goiter—An enlargement of the thyroid gland due to insufficient iodine in the diet.

Hyperthyroidism—Abnormal overactivity of the thyroid gland. People with hyperthyroidism are hypermetabolic, lose weight, exhibit nervousness, have muscular weakness and fatigue, sweat heavily, and have increased urination and bowel movements. This condition is also called thyrotoxicosis.

Hypothyroidism—Abnormal underfunctioning of the thyroid gland. People with hypothyroidism have a lowered body metabolism, gain weight, and are sluggish.

Parathyroid glands—Two pairs of smaller glands that lie close to the lower surface of the thyroid gland. They secrete parathyroid hormone, which regulates the body's use of calcium and phosphorus.

Recurrent laryngeal nerve—A nerve that lies very near the parathyroid glands and serves the larynx or voice box.

Thyroid storm—An unusual complication of thyroid function that is sometimes triggered by the stress of thyroid surgery. It is a medical emergency.

Diagnosis

Thyroid disorders do not always develop rapidly; in some cases, the patient's symptoms may be subtle or difficult to distinguish from the symptoms of other disorders. Patients who have **hypothyroidism** are sometimes misdiagnosed as having a psychiatric depression. Before a thyroidectomy is performed, a variety of tests and studies are usually required to determine the nature of the thyroid disease. Laboratory analysis of blood determines the levels of active **thyroid hormones** circulating in the body. The most common test is a blood test that measures the level of thyroid-stimulating hormone (TSH) in the bloodstream. Sonograms and **computed tomography scans** (CT scans) help to determine the size of the thyroid gland and location of abnormalities. A nuclear medicine scan may be used to assess thyroid function or to evaluate the condition of a thyroid nodule, but it is not considered a routine test. A needle biopsy of an abnormality or aspiration (removal by suction) of fluid from the thyroid gland may also be performed to help determine the diagnosis.

Preparation

If the diagnosis is hyperthyroidism, a person may be asked to take antithyroid medication or iodides before the operation. Continued treatment with antithyroid drugs may be the treatment of choice. Otherwise, no other special procedure must be followed prior to the operation.

WWW.BOOKBAZ.IR

Aftercare

A thyroidectomy incision requires little to no care after the dressing is removed. The area may be bathed gently with a mild soap. The sutures or the metal clips are removed 3–7 days after the operation.

Risks

There are definite risks associated with the procedure. The thyroid gland should be removed only if there is a pressing reason or medical condition that requires it.

As with all operations, people who are obese, smoke, or have poor **nutrition** are at greater risk for developing complications related to the general anesthetic itself.

Hoarseness or voice loss may develop if the recurrent laryngeal nerve is injured or destroyed during the operation. Nerve damage is more apt to occur in people who have large goiters or cancerous tumors.

Hypoparathyroidism (underfunctioning of the parathyroid glands) can occur if the parathyroid glands are injured or removed at the time of the thyroidectomy. Hypoparathyroidism is characterized by a drop in blood **calcium** levels resulting in **muscle cramps** and twitching.

Hypothyroidism (underfunctioning of the thyroid gland) can occur if all or nearly all of the thyroid gland is removed. Complete removal, however, may be intentional when the patient is diagnosed with cancer. If a person's thyroid levels remain low, thyroid replacement medications may be required for the rest of his or her life.

A hematoma is a collection of blood in an organ or tissue, caused by a break in the wall of a blood vessel. The neck and the area surrounding the thyroid gland have a rich supply of blood vessels. Bleeding in the area of the operation may occur and be difficult to control or stop. If a hematoma occurs in this part of the body, it may be life-threatening. As the hematoma enlarges, it may obstruct the airway and cause a person to stop breathing. If a hematoma does develop in the neck, the surgeon may need to perform drainage to clear the airway.

Wound infections can occur. If they do, the incision is drained, and there are usually no serious consequences.

Results

Most patients are discharged from the hospital 1–4 days after a thyroidectomy. Most resume their normal activities two weeks after the operation. People who have cancer may require subsequent treatment by an oncologist or endocrinologist.

Morbidity and mortality rates

The mortality of thyroidectomy is essentially zero. Hypothyroidism is thought to occur in 12–50% of persons in the first year after a thyroidectomy. Late-onset hypothyroidism develops among an additional 1–3% of persons each year. Although hypothyroidism may recur many years after a partial thyroidectomy, 43% of recurrences occur within five years.

Mortality from thyroid storm, an uncommon complication of thyroidectomy, is in the range of 20–30%. Thyroid storm is characterized by **fever**, weakness and wasting of the muscles, enlargement of the liver, restlessness, mood swings, change in mental status, and in some cases, **coma**. Thyroid storm is a medical emergency requiring immediate treatment. After a partial thyroidectomy, thyroid function returns to normal in 90–98% of persons.

Alternatives

Injections of radioactive iodine were used to destroy thyroid tissue in the past. This alternative is rarely performed.

Thyroiditis

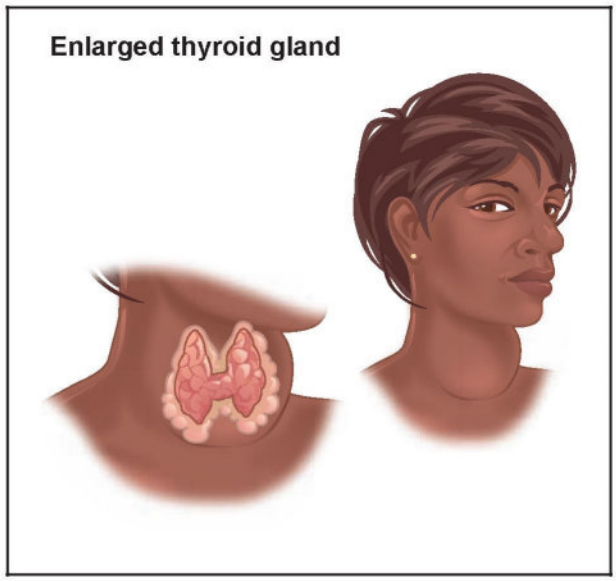
Definition

Thyroiditis is inflammation of the thyroid gland, a butterfly-shaped organ next to the windpipe.

Description

The thyroid is the largest gland in the neck. It produces, secretes, and stores thyroxine (T_4), a hormone that influences the metabolism of just about every body process.

When the thyroid gland is functioning properly, hormone release is carefully regulated. When bacteria or viruses invade and inflame the gland, T_4 surges into the bloodstream and raises hormone levels that then discourage the gland from creating more T_4.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Eventually the hormone stores are exhausted, the thyroid loses its ability to manufacture T_4, and an underactive thyroid (**hypothyroidism**) results.

The major cause of hypothyroidism, thyroiditis affects about 12 million people in the United States. This condition is more common in women than in men and usually develops between ages 30–50.

Hashimoto's disease

The most common type of thyroiditis is Hashimoto's disease, a painless disorder also known as:

- autoimmune thyroiditis
- chronic lymphocytic thyroiditis
- lymphadenoid goiter
- struma lymphomatosa

Hashimoto's disease can develop at any age, but is most common in middle-aged women. This immune system disorder runs in families, and affects about 5% of adults in the United States.

Hashimoto's disease slowly destroys thyroid tissue and robs the gland of its ability to change iodine into T_4. The condition progresses so gradually that many people who have it do not realize anything is wrong until the enlarged gland forms a **goiter**, a swelling seen and felt in the front of the neck. This may not happen until weeks or even years after an individual develops Hashimoto's.

WWW.BOOKBAZ.IR

Subacute thyroiditis

Much less common than Hashimoto's disease, subacute thyroiditis is a painful inflammation that develops suddenly in a patient who has had a viral infection, such as **mumps** or an upper respiratory illness. **Pain** radiates throughout the neck and patients feel ill and feverish. It may take as long as several months for normal thyroid function to resume.

Subacute thyroiditis is also called:

- DeQuervain's thyroiditis
- giant cell thyroiditis
- granulomatous thyroiditis
- subacute granulomatous thyroiditis

Silent thyroiditis

The least common of the three major types, silent thyroiditis is characterized by rigidity and slight enlargement of the thyroid gland. Postpartum thyroiditis, a form of silent thyroiditis, develops in 5–9% of all women who have recently given birth. Postpartum thyroiditis develops within a year of the baby's birth and disappears within six months.

Acute thyroiditis

Caused by acute infection, this rare disease is a medical emergency. A patient who has acute thyroiditis has a high **fever** and feels very ill. The neck is red, hot, and very tender.

Causes and symptoms

Hashimoto's disease

Hashimoto's disease develops when the immune system attacks the thyroid gland. It may be related to such hormone-related (endocrine system) disorders as:

- Addison's disease. This condition, caused by malfunction of the adrenal gland, is characterized by weakness, loss of weight and appetite, and increased sensitivity to cold.
- Diabetes mellitus. This metabolic disorder is caused by a lack of insulin production or by the body's inability to process insulin.
- Graves' disease. This disease is the most common form of hyperthyroidism.
- Vitiligo. This is a noncancerous skin disease characterized by unpigmented patches of skin.

Being female and having a family history of Hashimoto's thyroiditis increases the likelihood of developing the disease. Its symptoms include:

- constipation
- fatigue
- goiter or enlarged neck
- inability to tolerate cold temperatures
- weight gain, some patients' faces swell and their joints stiffen

Subacute thyroiditis

Characterized by painful gland enlargement that is sometimes mistaken for a **sore throat** that may last for months, subacute thyroiditis often follows:

- influenza
- mumps
- upper respiratory infections
- viruses that produce cold symptoms and inflammation of the membrane that protects the brain (meningitis), inflammation of the sac that surrounds the heart (pericarditis), inflammation of the heart muscle (myocarditis), and other diseases.

People who have subacute thyroiditis feel feverish, weak, and tired. The thyroid is sore to the touch. They may be nervous, sweat, and have trouble tolerating heat or swallowing. Symptoms of subacute thyroiditis also include:

- rapid heartbeat
- tremors
- weight loss

Silent thyroiditis

The cause of silent thyroiditis is uncertain, but the condition is believed to be an immune-system disorder triggered by **childbirth**. Although silent thyroiditis is painless, the condition's other symptoms are similar to those of subacute thyroiditis. The thyroid gland enlarges only slightly, and the eyes do not bulge.

Diagnosis

Family physicians and endocrinologists usually base a diagnosis of thyroiditis on:

- blood levels of thyroid hormones, thyroid-stimulating hormone, and anti-thyroid antibodies
- personal and family medical history
- the appearance of a patient's thyroid gland

Thyroid antibodies present in 95% of patients with Hashimoto's thyroiditis make it possible to diagnose this disease without surgery or biopsy. A blood test that measures sedimentation rate, an indication of the extent of inflammation, is a useful tool for diagnosing subacute thyroiditis.

Treatment

Medical therapy for thyroiditis includes:

- antibiotics to fight infection
- high doses of aspirin to relieve inflammation
- hormones to suppress or replace thyroid function
- pain medications

Cortisone drugs are sometimes prescribed to reduce persistent inflammation. In rare instances, surgery can be used to drain infection or relieve pressure near the thyroid gland.

Hashimoto's disease

The goal of treatment for Hashimoto's disease is to prevent the thyroid gland from getting larger. Regular monitoring may be the only treatment indicated for patients whose gland is only slightly enlarged, and who show no signs of hormone deficiency. Levothyroxine (Synthroid) may be prescribed to correct hormone deficiency in a patient who has a large goiter.

Subacute thyroiditis

The goal of treatment for subacute thyroiditis is to relieve pain, reduce inflammation, and regulate **hyperthyroidism**. Bed rest and **beta blockers** (propranolol, naldolol) may be necessary until thyroid activity is controlled, and the patient may have to take:

- anti-inflammatory medication for several weeks
- high doses of aspirin
- other analgesics

If subacute thyroiditis continues for a long time, cortisone and thyroid hormone medication may be prescribed to relieve inflammation and allow the gland to rest. Glucocorticoids (prednisone) are prescribed for symptoms that do not respond to other treatment. The original problem often becomes more pronounced after these medications are discontinued.

Silent thyroiditis

Most patients who have silent thyroiditis do not need any treatment, but:

- bed rest and beta blockers are occasionally needed to regulate rapid heart beat
- inderal (propanolol) may be prescribed for brief periods of hyperthyroidism
- steroids may be prescribed for severe episodes of acute inflammation

KEY TERMS

Addison's disease—A disease that results from a deficiency in adrenocortical hormones.

Diabetes mellitus—A disorder of the pancreas. This chronic disorder of carbohydrate metabolism results in hyperglycemia and glycosuria.

Goiter—An abnormal enlargement of the thryroid gland.

Graves' disease—Also called hyperthyroidism, this disease results from overactivity of the thyroid gland.

Subacute—An abnormal condition present in a person who appears to be clinically well.

Vitiligo—A benign skin disease that results in irregular patches of skin that are totally lacking in color.

Acute thyroiditis

Acute thyroiditis requires emergency treatment with **antibiotics** and surgery.

Prognosis

Thyroiditis usually responds to treatment, and some patients recover normal thyroid function without treatment. Because permanent loss of thyroid function is a possibility and life-long thyroid replacement therapy may be necessary, regular medical monitoring should continue even after the patient has apparently recovered.

Hashimoto's disease

Some cases of Hashimoto's disease remain stable for years. Others slowly progress to hypothyroidism, which is treated with thyroid **hormone replacement therapy**.

Subacute thyroiditis

Most patients with subacute thyroiditis recover fully after no more than a few months. This condition occasionally recurs, but severe or long-term complications are rare.

Silent thyroiditis

Four of every five patients with silent thyroiditis recover completely within three months. The thyroid status of these patients should be evaluated within 12 months. Because silent thyroiditis recurs in 10% of patients within three years and may progress to

WWW.BOOKBAZ.IR

hypothyroidism, medical monitoring should continue for three years after recovery appears complete.

Prevention

Flu shots or immunizations for **measles**, mumps, and **rubella** may help prevent conditions associated with subacute thyroiditis. There is no known way to prevent other forms of thyroiditis.

Tilt table test

Definition

The tilt table test is a test in which a patient is positioned in a supine position and brought to a predetermined angle or angles from the horizontal position. Such positioning helps to determine the cause of any decrease in oxygen to the brain. Different types of drugs may also be used in the testing process.

Purpose

The purpose of the tilt table test is to help determine appropriate therapy for individuals with **fainting** (syncope) and presyncope of unexplained origin.

Precautions

Precautions are few with the tilt table test. However, when any drug is used with this test, the appropriate precautions for that particular drug should be observed. For example, when isoproterenol or similiar drugs are used during the tilt table test, the taking of non-prescription drugs for **asthma**, **cough**, cold, or allergy; appetite suppressants; sleeping pills; or drugs containing **caffeine** should be made known to the physician prior to the test. Likewise, the physician should be informed of any **allergies** to any sympathomimetic drugs, including several of the diet pills on the market. The physician should be told of any serious heart-rhythm disorders.

Description

Syncope is described as a pathological brief loss of consciousness caused by a temporary deficiency of oxygen in the brain. Previous studies have shown the effectiveness of tilt table testing in establishing the diagnosis of neurocardiogenic syncope, and in dictating therapy in patients with syncope of unknown origin. Despite its usefulness, small numbers of patients and brief followup reports have limited the majority of studies. Sensitivity-enhancing techniques, such as the administration of isoproterenol, are applied in specific cases to children and young adults to compensate for the otherwise low sensitivity (20-30%) observed in that population.

Preparation

In order for a patient to make informed decisions about any diagnostic test or procedure, there are important questions that need to be asked prior to the procedure. The information gained will be helpful for that patient in determining benefits, risks, and cost of the procedure, and alternatives. The patient should understand the purpose of the tilt table test, and the diagnosis that the physician is trying to confirm or rule out. If the tilt table test is positive, the patient should ask questions about the frequency of false-positive results for that particulare tilt table procedure, and should inquire about the next step in treatment.

Aftercare

After the procedure, the patient is asked to transfer from the supine position to a sitting position, and is observed for a short period of time. During this time and after several minutes in the sitting position, any symptoms of **dizziness** and vertigo are noted. When ready, the individual transfers from the sitting position to standing. After additional observation and taking of vital signs, the individual is allowed to go home.

Risks

Risks of the tilt table test are low, but do include significant changes in blood pressure while in the

KEY TERMS

Sympathomimetic—Denoting a drug that mimics the effects of stimulation of organs and structures by the sympathetic nervous system. The sympathetic nervous system pertains to the part of the nervous system originating in the thoracic and lumbar regions of the spinal cord. In general, it inhibits or opposes the physiological effects of another aspect of the nervous system, as in tending to reduce digestive secretions, speed up the heart, and contract the blood vessels.

Syncope—A loss of consciousness over a short period of time, caused by a temporary lack of oxygen in the brain.

Vertigo—The sensation of dizziness.

supine position, and any adverse reactions to any drugs administered during the tilt table test.

Results

Normal results of the tilt table test should help the physician in assessing what may or may not be the cause of the syncope.

Abnormal results

Abnormal results include any pathologic reactions to the position changes or sensitivity enhancing techniques, such as the administration of isoproterenol or other related drugs.

Tinnitus

Definition

Tinnitus is hearing ringing, buzzing, or other sounds without an external cause. Patients may experience tinnitus in one or both ears or in the head.

Description

Tinnitus affects as many as 40 million adults in the United States. It is defined as either objective or subjective. In objective tinnitus, the doctor can hear the sounds, as well as the patient. Objective tinnitus is typically caused by tumors, turbulent blood flow through malformed vessels, or by rhythmic muscular spasms. Most cases of tinnitus are subjective, which means that only the patient can hear the sounds.

Causes and symptoms

Subjective tinnitus is frequently associated with **hearing loss**. About 90% of patients have sensorineural hearing loss; 5% have conductive hearing loss; 5% have normal hearing. The causes of subjective tinnitus include:

- impacted ear wax
- ear infections
- hardening of the structures of the inner ear
- hearing loss related to age or excessive noise
- ototoxic medications, including aspirin, quinine, some diuretics, heavy metals, alcohol, and certain antibiotics
- Ménière's syndrome
- head trauma
- systemic diseases, including syphilis, hypertension, anemia, or hypothyroidism
- tumors of the ear

Diagnosis

Diagnosis of tinnitus includes a **physical examination** of the patient's head and neck. The doctor will use an otoscope to examine the ears for wax, infection, or structural changes. He or she will also use a stethoscope to listen to the blood vessels in the neck.

Tuning fork tests

The Rinne and Weber tests are commonly used to evaluate the type and severity of hearing loss. In the Weber test, the doctor holds a tuning fork against the patient's forehead or front teeth. If the hearing loss is sensorineural, the sound radiates to the ear with better hearing; if the hearing loss is conductive, the sound will be louder in the damaged ear. In the Rinne test, the tuning fork is placed alternately on the mastoid bone (behind the ear) and in front of the ear. In conductive hearing loss, bone conduction (BC) is greater than air conduction (AC). In sensorineural hearing loss, AC is greater than BC.

WWW.BOOKBAZ.IR

KEY TERMS

Conductive hearing loss—Hearing loss caused by loss of function in the external or middle ear.

Meniere's syndrome—A disease of the inner ear, marked by recurrent episodes of loss of balance (vertigo) and roaring in the ears lasting several hours. Its cause is unknown.

Ototoxic—Damaging to the nerves controlling the senses of hearing and balance.

Sensorineural hearing loss—Hearing loss caused by damage to the nerves or parts of the inner ear governing the sense of hearing.

Diagnostic imaging

Magnetic resonance **angiography** or **venography** (MRA and MRV) can be used to evaluate malformations of the blood vessels. **Computed tomography scans** (CT scans) or **magnetic resonance imaging** scans (MRIs) can be used to locate tumors or abnormalities of the brain stem.

Blood tests

The doctor may order a **complete blood count** (CBC) with specific antibody tests to rule out **syphilis** or immune system disorders.

Treatment

Some cases of tinnitus can be treated by removal of the underlying cause. These include surgical treatment of impacted ear wax, tumors, head injuries, or malformed blood vessels; discontinuance of ototoxic medications; and antibiotic treatment of infections.

Subjective tinnitus, especially that associated with age-related hearing loss, can be treated with **hearing aids**, noise generators or other masking devices, **biofeedback**, antidepressant medications, or lifestyle modifications (elimination of **smoking**, coffee, and **aspirin**).

Alternatives

A variety of alternative therapies may be helpful in the treatment of tinnitus. Dietary adjustments, including the elimination of coffee and other stimulants, may be useful, since stimulants can make tinnitus worse. In addition, reducing the amount of fat and **cholesterol** in the diet can help improve blood circulation to the ears. Nutritional supplementation with vitamin C, **vitamin E**, B **vitamins**, **calcium**, magnesium, potassium, and essential fatty acids is also recommended. Gingko (*Gingko biloba*) is often suggested, since it is believed to enhance circulation to the brain. **Acupuncture** treatments may help decrease the level of tinnitus sounds the patient hears, and constitutional homeopathic treatment may also be effective.

Prognosis

The prognosis depends on the cause of the tinnitus and the patient's emotional response. Most patients with subjective tinnitus do not find it seriously disturbing, but about 5% have strong negative feelings. These patients are frequently helped by instruction in relaxation techniques.

Tissue typing

Definition

Tissue typing is a group of procedures that determines the type of histocompatibility antigens on a person's cells or tissues. This procedure is typically used prior to transplantation of tissues or organs.

Purpose

Tissue typing is done prior to transplantation to ensure as close a match as possible between the donor and the recipient. If the histocompatibility antigens do not match well, there is a much greater chance that the recipient will reject the donated tissue.

Histocompatibility antigens are molecules on the surface of all cells in the body. The specific types of histocompatibility antigens present on a person's cells determine their identity and distinguish each person. They are a "fingerprint."

Each person has a unique set of histocompatibility antigens. If the antigens on tissue or organs from a donor do not match that of the recipient, a rejection

KEY TERMS

Antibody—A molecule produced by the body that is part of the immune response to attack antigens.

Antigen—A molecule that causes the body to produce an immunological response to attack the antigen.

Cornea—The transparent outer layer of the eye. It covers the iris and lens.

Lymphocyte—A class of white blood cells that are responsible for creating the immune response to antigens.

response can occur. The recipient's immune system will detect the difference between the two sets of antigen and start a rejection response to kill the donated tissue. Except in the case of identical twins, no two people are identical in terms of their histocompatibility antigen types. However, the closer two tissues come to matching, the more likely the recipient will accept the donated tissue or organ.

Human lymphocyte antigens (HLA) is the name given to the most commonly used histocompatibility antigens. The antigens can be grouped into two classes: class I antigens are found on almost all cells, and class II antigens are normally found only on B lymphocytes, macrophages, monocytes, dendritic cells, and endothelial cells.

Description

Generally, typing is performed on blood cells because they are an easy sample to obtain. Blood is withdrawn from a vein in the forearm, and the cells are separated. There are a number of different techniques used to identify the antigens on the cells. Typically, specific antibodies react with the cells. Each antibody preparation is specific for one histocompatibility antigen. If the antigen is present, the antibody will bind to it. Laboratory instruments are used to detect antibody binding to the cells. Class II antigens are determined by the mixed lymphocyte reaction (MLR) or by a polymerase chain reaction (PCR). In the mixed lymphocyte reaction, lymphocyte replication occurs if there is a mismatch, and is detected by a specific assay. The PCR test is a new DNA-based test that can detect the presence or absence of antigens by determining whether cells have the genes for the antigens.

One type of transplant does not require tissue typing. In the case of corneal transplants, tissue typing is not needed because cornea do not have their own blood supply. This greatly reduces the chance that immune cells will come in contact with the cornea and recognize it as foreign. For this reason, corneas can be transplanted from any person, and there is little chance of rejection.

Results

Because each person has their own histocompatibility antigen "fingerprint," there is no true normal result. Each fingerprint is unique.

Tommy John surgery

Definition

Tommy John surgery is an elective surgical graft procedure to replace a ligament in the elbow damaged by overuse, most often in playing baseball at the collegiate or professional level. It is named for the former pitcher for the Los Angeles Dodgers who was the first to undergo this procedure in 1974. Also known as ulnar collateral ligament (UCL) reconstruction, this procedure involves replacing the ligament that joins the humerus (the long bone in the upper arm) to the ulna (the heavier of the two long bones in the forearm) with a ligament or tendon taken from another location in the patient's body. The tissues most commonly used to replace the UCL are the palmaris tendon from the forearm or the gracilis tendon from the groin.

Description

Injuries to the ulnar collateral ligament range from minor tears and inflammation to complete rupture of the ligament. The symptoms of injury to the UCL include **pain** on the inside of the elbow, looseness or

WWW.BOOKBAZ.IR

instability in the elbow joint, difficulty throwing a baseball or other object, and a tingling in the ring finger or little finger caused by irritation of the ulnar nerve. The doctor can sometimes diagnose a UCL injury simply by taking a careful patient history and examining the elbow in the office, but is more likely to order a CT scan, or an MRI following an injection of gadolinium into the affected elbow, to confirm the office diagnosis.

The patient is completely anesthetized before Tommy John surgery. The surgeon removes a ligament from the patient's wrist, forearm, thigh, knee, or hip. After making an incision in the skin of the elbow, the surgeon drills two holes, one in the lower end of the humerus and the other in the upper end of the ulna. The damaged UCL is removed and the new ligament is threaded through the holes in a figure-eight pattern and anchored. The ulnar nerve is moved to prevent scar tissue from putting pressure on it. The incision is then closed and the elbow protected with a splint for 7–10 days.

Purpose

Tommy John surgery is done to correct overuse injuries to the elbow that have not responded to more conservative treatments, which usually include resting the joint, applying ice, taking **nonsteroidal anti-inflammatory drugs** (NSAIDs) to reduce discomfort, and undergoing **physical therapy**. Tommy John surgery is considered an elective rather than an emergency procedure, and a treatment of last resort because the patient will typically miss a minimum of several months of participation in his or her sport.

Although Tommy John surgery is commonly associated with baseball players, it has been performed on athletes in other sports that involve repeated overhand throwing motions, such as javelin throwers, gymnasts, soccer and football players, cheerleaders, and tennis players.

Preparation

Preparation for Tommy John surgery is similar to that for other elective surgical procedures performed in a hospital. The patient is usually asked to have a complete medical examination with his or her primary care physician several weeks before surgery, and blood and urine samples are taken. The surgeon also takes a complete medical history, including a list of previous surgeries

(if any), and the patient's current medications, including over-the-counter and herbal preparations. The patient will be asked to stop **smoking** if he or she presently uses tobacco, and to stop taking **aspirin** or any arthritis medications about two weeks before surgery to lower the risk of excessive bleeding. The patient is treated for any active infections before entering the hospital.

Aftercare

The patient usually stays in the hospital overnight following Tommy John surgery and will be given a course of **antibiotics** to prevent infection. Full recuperation from the operation usually takes several months to a full year for strength and range of motion to return. Some athletes need as much as two full years following Tommy John surgery to return to their previous level of play.

Physical therapy is a crucial part of **rehabilitation** following the Tommy John procedure. Most patients will be given a set of gentle range-of-motion exercises to perform shortly after returning home. Professional athletes typically follow a three-stage pattern of rehabilitation following Tommy John surgery, with the first stage consisting of gentle range-of-motion exercises while wearing an elbow brace; after 6–8 weeks, a second stage consisting of elbow-strengthening exercises; and a third stage beginning to toss a ball and eventually returning to the mound. Pitchers should not return to professional play until nine months to a year after surgery, while position players can usually return to competition after six months of rehabilitation.

Aftercare also includes making arrangements for help at home, as patients will ordinarily be unable to reach for objects on high shelves or lift any significant amount of weight for at least six weeks after surgery, and should not drive or operate heavy equipment as long as they are taking medications for severe pain.

Results

Tommy John surgery has a high rate of success, with 85–92% of athletes being able to return to their sport after rehabilitation. Some athletes in throwing sports even exceed their previous level of performance after Tommy John surgery. Tommy John himself had 14 successful seasons as a major league pitcher after he returned for the 1976 season following his rehabilitation.

Risks

The risks of Tommy John surgery are similar to those of other surgical procedures requiring local or general **anesthesia**. They include:

- infection
- pain
- bleeding
- need for further surgery
- possible prolonged rehabilitation
- damage to nerves and blood vessels in the elbow, particularly the ulnar nerve
- loss of strength or flexibility in the elbow
- loosening or rupture of the replacement ligament

KEY TERMS

Gadolinium—A rare-earth metal that is used as a contrast agent in MRI imaging.

Humerus—The long bone of the upper arm that runs from the shoulder blade to the elbow joint.

Ulna—The longer of the two bones in the forearm, extending from the medial side of the elbow joint to the side of the wrist closest to the little finger.

Ulnar collateral ligament (UCL) reconstruction—The medical name for the Tommy John procedure.

Ulnar nerve—The nerve that runs close to the ulna and innervates the little finger and ring finger. The longest unprotected nerve in the human body, it is the nerve that aches or tingles when a person hits their "funny bone."

Tomosynthesis

Definition

Tomosynthesis—also known as digital breast tomosynthesis (DBT) or 3-D mammography—is a new form of **mammography** that allows higher-resolution limited-angle tomography at radiation levels that are safe for use in breast examinations. The x-ray machine used in tomosynthesis is similar to a CT scan in that it takes a number of x-ray images of breast tissue from different angles. The different images are then assembled in a computer to form a composite three-dimensional image of the breast tissue. The English word *tomosynthesis* is derived from two Greek words that mean "slice" or "section," and "putting together."

Description

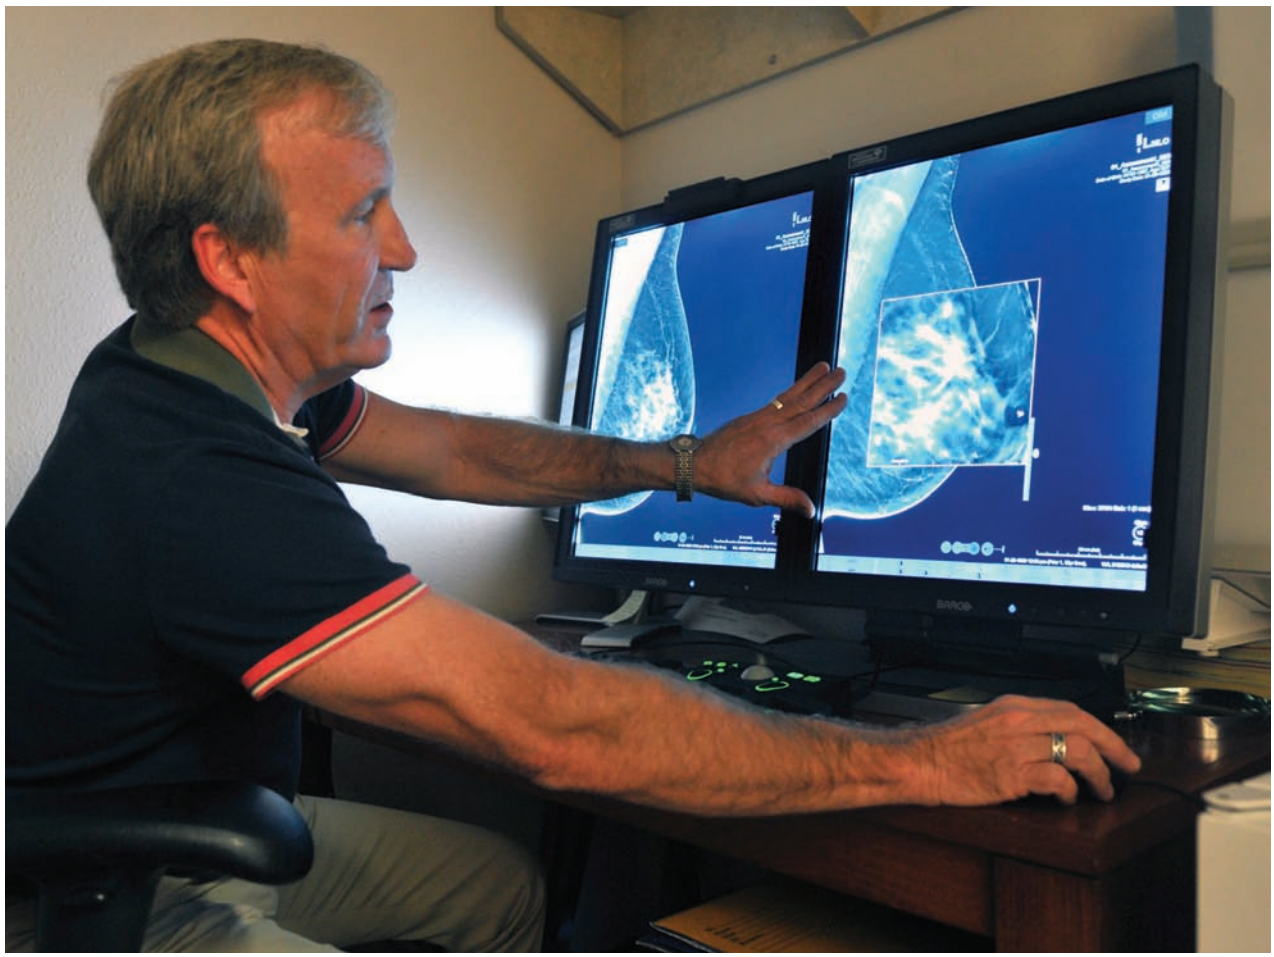
Tomosynthesis is a new imaging technology in mammography that allows three-dimensional x-ray images of breast tissue to be developed and stored in digital format, in contrast to the two-dimensional images of conventional mammograms. Tomosynthesis has been used in Europe for breast examinations since 2008 but was not approved by the Food and Drug Administration (FDA) for use in the United States until February 2011. At first limited to a few major medical centers, it is now widely available across the United States and Canada. It can be used to diagnose **breast cancer** in men as well as in women.

The major difference between tomosynthesis and a two-dimensional mammogram is that in tomosynthesis the x-ray arm of the mammogram machine is not stationary. It moves in a 15° arc over the breast for a period of about 4 seconds. During the exposure, the machine produces and stores 11 images taken at 1-second intervals. Each image represents a 1-mm section of the breast. The radiologist then reads the images in succession to obtain a full three-dimensional view of the breast, as compared to the two flat images produced in a standard mammogram.

A patient scheduled for tomosynthesis will be asked to stand in front of the x-ray machine as she would for a conventional mammogram. As with a conventional mammogram, the patient's breast is compressed between two plates and she is asked to hold her breath while the technician activates the x-ray machine. The exposure takes between 4 and 10 seconds. The patient will not feel the radiation. The entire examination should take no more than 15–30 minutes, including undressing before the examination and providing the doctor or technician with any needed information.

Purpose

Tomosynthesis is a new technology used for the early diagnosis of breast cancer in women. It can be used for both screening and diagnostic mammography as a replacement for conventional two-dimensional mammograms. Because tomosynthesis produces clearer images than conventional mammograms, it has been reported to improve detection of early-stage breast cancers by 15%. It also reduces the number of callbacks by as much as 40%, thus sparing many



Radiologist Dr. Paul Bice compares an image from 2-D technology mammogram to the new 3-D digital tomosynthesis mammography. women the **anxiety** associated with having to undergo a second mammogram or another form of diagnostic imaging.

Preparation

Women preparing for a breast examination by tomosynthesis should prepare as they would for a two-dimensional mammogram:

- Wear a two-piece outfit on the day of the examination so that only the clothing on the upper body needs to be removed, and be prepared to remove all jewelry before the examination.
- Do not use talcum powder, deodorant, antiperspirant, oils, or creams on the upper body before the examination. The patient can take these items in her handbag and apply them after the mammogram if desired.
- Tell the doctor or technician about previous mammograms taken at other imaging facilities to allow comparison with the new images.
- Describe any problems with the breasts to the technician before the examination, and also inform the technician if breast implants are present.
- Consider restricting caffeine intake for two weeks before the examination if the breasts are unusually sensitive.
- Premenopausal women should schedule the examination for the week following their menstrual period to minimize breast tenderness.
- Pregnant or lactating women should inform the doctor of their condition, as the doctor may recommend another type of breast examination to avoid exposing the baby to radiation.
- Women with extremely large breasts may not be eligible to be examined by tomosynthesis.

KEY TERMS

Callback—A follow-up examination for a patient whose initial mammogram (or other imaging test) yielded unclear results.

Tomography—In general, any kind of diagnostic image obtained as sections through the use of a penetrating wave. Tomosynthesis is a specific form of tomography.

Aftercare

No aftercare is necessary. The patient can get dressed and leave the clinic as soon as the examination is completed.

Results

The results of a breast examination by tomosynthesis are evaluated by a radiologist, who is a physician with specialized training in interpreting x-ray images. The radiologist will read the digital images and send a report to the patient's primary care physician and/or gynecologist. It takes about a day to interpret the images and report the findings.

If the radiologist finds suspicious or abnormal areas on the images, the patient will be called back for a second mammogram, an **ultrasound**, an MRI of the breast, or a biopsy. In most cases (75–80%) no cancer is found; suspicious findings on the initial mammogram are termed false positives.

Risks

The risks to patients from exposure to the radiation required for tomosynthesis are minimal because the amount of radiation required is low—about the same as the level of background radiation that a person would absorb during a weekend visit to a large city like New York, or flying several thousand miles in an airplane. Nonetheless, women who are pregnant or nursing should inform the doctor and technician of their condition.

The major risk associated with tomosynthesis—as with a conventional mammogram is a so-called false negative; that is, that an early-stage breast cancer is not detected even though it is present in the breast. False negatives are most likely to occur in younger women and in women with dense breast tissue; some early-stage cancers do not appear on a mammogram at all while others are hidden by unusually dense breast tissue. Dense breast tissue has been established as an independent risk factor for breast cancer as well as posing difficulties for early detection of it. The false negative rate is estimated to be around 15–20%; thus a "normal" result does not mean that the woman can assume she is cancer-free.

Tonsil removal *see* **Tonsillectomy and adenoidectomy**

Tonsillectomy and adenoidectomy

Definition

Tonsillectomy and adenoidectomy (T & A) are surgical procedures to remove the tonsils from the back of the mouth or adenoids from the back of the nasal cavity—both are part of the lymphatic system, which is responsible for fighting infection. These operations are often performed together and are usually done on children. T & As are the most common childhood operations.

Purpose

Tonsillectomy

Tonsils are removed (with or without the adenoids) when the child has any of the following conditions:

- obstruction
- sleep apnea. This is a condition in which the child snores loudly and stops breathing temporarily at intervals during sleep
- inability to swallow properly because of enlarged tonsils
- "hot potato" voice (breathy voice) and other speech abnormalities due to enlarged tonsils
- recurrent or persistent abscesses or throat infections

Doctors do not agree completely on the number of sore throats that make a tonsillectomy necessary. Most would agree that four cases of **strep throat** in any one year; six or more episodes of **tonsillitis** in one

year; or five or more episodes of tonsillitis per year for two years indicate that the tonsils should be removed.

Adenoidectomy

Adenoids are removed (with or without the tonsils) when the child has any of the following conditions:

- alteration of facial growth because of enlarged adenoids
- upper airway obstruction
- development of an irregular bite (dental malocclusion)
- difficult speech or swallowing

Precautions

T & As are not performed as frequently today as they were in the past. One reason for a more conservative approach is that there is always some risk involved when a patient is put under general **anesthesia**.

In some cases, a T & A may need to be modified or postponed:

- children with cleft palates should not have the adenoids removed
- bleeding disorders; these must be brought under control before surgery
- acute tonsillitis; surgery should be postponed—usually for three to four weeks—until the infection is gone

Description

Tonsillectomies are hospital procedures. In adults, they may be performed under local anesthesia. Children are usually placed under general anesthesia. The doctor depresses the tongue in order to see the throat and removes the tonsils with a scooplike instrument. The adenoids are usually removed through the nose.

Aftercare

Patients are turned on the side after the operation to prevent the possibility of blood being drawn into the lungs. The patient's vital signs are checked. After the patient is fully awake, he or she can drink water and other nonirritating liquids.

Adult patients are usually warned to expect some bleeding after the operation and a very **sore throat**. **Antibiotics** are given to prevent infection. Medications to relieve **pain** may also be given. For at least the first 24 hours, the patient is fed soft or pureed foods and fluids. If the adenoids alone were removed, the patient may be allowed solid food the day after surgery.

KEY TERMS

Abscess—A localized area of tissue destruction and pus formation.

Adenoids—Masses of lymphoid tissue that are found in the upper throat.

Sleep apnea—A condition marked by loud snoring during sleep and periodic episodes of suspended breathing.

Tonsils—Oval masses of lymphoid tissue on each side of the throat.

Patients are usually sent home the next day, with instructions to call the doctor if there is bleeding, an earache, or a **fever** that lasts longer than three days. They are told to expect a white scab to form in the throat 5–10 days after surgery.

Risks

About one in every 15,000 tonsillectomies ends in death, either from the anesthesia or from bleeding to death 5–7 days after the operation. There is also a chance that children with previously normal speech will develop a nasal-sounding voice. In addition, children younger than five years may be emotionally upset by the hospital experience.

Results

Normal results include the correction of the condition for which the surgery was performed.

Tonsillitis

Definition

Tonsillitis, also known as tonsillar infection and sometimes as pharyngitis, is an inflammation of the tonsils at the back of the throat (the palatine tonsils) caused by infection by a virus or bacterium. The tonsils themselves are three pairs of clumps of lymphoid

tissue; they are part of the lymphatic system and act as part of the immune system. Tonsillitis may be caused by either viruses (about 75% of cases) or bacteria (the remaining 25%).

Recurrent tonsillitis is defined as seven episodes of tonsillitis in one year; five episodes in two successive years; or three infections per year for three straight years.

Demographics

Tonsillitis is a common illness among children in the United States; nearly all have at least one episode of tonsillitis by the time they reach the teen years, although tonsillitis is rare in children younger than two. Recurrent tonsillitis is less common than single episodes, occurring in 11–13% of children.

Tonsillitis caused by bacteria is most common in children between the ages of five and 15, while children younger than five are more likely to have viral tonsillitis. As far as is known, tonsillitis affects boys and girls equally, and is equally common in all races and ethnic groups in the United States.

Description

The tonsils include three pairs of masses of lymphoid tissue located toward the back of the mouth and the upper part of the throat cavity: the palatine tonsils, which can be seen at the back of the throat and are the tonsils most often affected by tonsillitis; the lingual tonsils, located on the upper surface of the base of the tongue; and the adenoids, situated at the very back of the nasal cavity where the nose opens into the upper mouth. The tonsils function as part of the immune system to protect the body against infections of the throat and upper respiratory tract. These areas of tissue normally function to filter out disease organisms before they reach the lower throat; however, they can be overwhelmed by a virus or bacterium. At that point the tonsils become red and swollen, and may develop abscesses, which are pus–filled pockets or swellings. The swelling in turn causes painful or difficult swallowing, **sore throat**, and the other characteristic symptoms of tonsillitis.

Whether caused by viruses or bacteria, all forms of tonsillitis are contagious. Tonsillitis usually spreads from person to person by contact with discharges from the nose or throat of an infected child or adult. It is often spread by carriers—children or adults who are infected by a disease agent but do not have any of the symptoms of the disease. It is thought that 3–11% of schoolchildren in Canada and the United States are carriers of the disease organisms that cause tonsillitis.

Risk factors

Risk factors for tonsillitis include:

- Age. Tonsillitis is most common in children from the preschool years to the mid–teenage years.
- Frequent exposure to germs in school or from living in overcrowded conditions.
- Malnutrition.
- Weakened immune system or taking medications that suppress the immune response to infections.

Causes and symptoms

Causes

About three–quarters of all cases of tonsillitis are caused by viruses, with the remaining quarter caused by bacteria. The most common virus that causes tonsillitis is the Epstein–Barr virus (EBV), which also causes **infectious mononucleosis**. Viral tonsillitis can also be caused by the **measles** virus, herpes virus (the virus that causes **cold sores**), or adenoviruses (viruses that also cause stomach flu). The most common organisms responsible for bacterial tonsillitis are Group A streptococci, the bacteria that cause **strep throat** and **scarlet fever**. A new concern is the identification of methicillin–resistant *Staphylococcus aureus* (MRSA) as a cause of tonsillitis in the United States.

Symptoms

The symptoms of tonsillitis may include:

- Sore throat.
- Pain in the ears.
- Fever and chills.

- Red, swollen tonsils.
- White or yellow patches on the tonsils.
- Pain or difficulty in swallowing.
- Bad breath.
- "Hot potato" (muffled or weak) voice.
- Laryngitis.
- Swollen lymph nodes in the neck.
- Tiredness and overall sick feeling.
- Difficulty breathing or disturbed sleep, if the tonsils are extremely swollen.

Young children who cannot describe how they feel may become unusually fussy, drool because of difficulty swallowing, or refuse to eat.

Diagnosis

Diagnosis of tonsillitis can be made by a family doctor or by an otolaryngologist, a doctor who specializes in ear, nose, and throat disorders.

Examination

The diagnosis of tonsillitis is made from the visible symptoms and a **physical examination** of the patient. The doctor will examine the eyes, ears, nose, and throat, looking at the tonsils for signs of swelling, redness, or a discharge. In most cases the doctor can use a tongue depressor to examine the child's teeth and mouth from front to back, but a fiberoptic laryngoscope may be necessary if the child is in such distress that he or she cannot open the mouth wide enough to allow the use of a tongue depressor even when the doctor is as gentle as possible. A careful examination of the throat is necessary to rule out **diphtheria** and other conditions that may cause a sore throat. The doctor will also gently feel the lymph nodes in the neck for signs of tenderness or neck stiffness, and will check the condition of the child's skin and the tissues lining the mouth for evidence of **dehydration**.

Tests

Since most sore throats in children are caused by viruses rather than bacteria, the doctor may

KEY TERMS

Abscess—A pus–filled pocket or swelling within infected tissue.

Adenoids—The uppermost pair of tonsils, located at the very back of the nasal cavity where the nose joins the upper part of the mouth.

Carrier—A person or animal who is infected with an infectious disease agent but displays no symptoms of the disease.

Group A streptococcus—A sphere–shaped bacterium that grows in long chains and causes strep throat as well as scarlet fever and some forms of tonsillitis.

Lingual tonsils—A pair of small tonsils located on the upper side of the base of the tongue.

Tonsillectomy—Surgical removal of the tonsils.

take a **throat culture** in order to test for the presence of streptococcal bacteria. A throat culture is performed by wiping a cotton swab across the tonsils and back of the throat, and sending the swab to a laboratory for culturing. *Streptococcus pyogenes*, the bacterium that causes strep throat, is the most common disease agent responsible for tonsillitis. Depending on what type of test is used for strep, the doctor may be able to determine within a few minutes if *S. pyogenes* is present. The quick tests for strep are not as reliable as a laboratory culture, which can take 24–48 hours. If the results of a quick test are positive, however, the doctor can prescribe **antibiotics** right away. If the quick test results are negative, the doctor can do a throat culture to verify the results and wait for the laboratory report before prescribing antibiotics.

A blood test may also be done to rule out a more serious infection or condition, and to check the patient's **white blood cell count** to see whether the body is responding to the infection. In some cases, the doctor may order blood tests for mononucleosis (the Monospot test), since about a third of patients with mononucleosis develop **streptococcal infections** of the tonsils.

Imaging studies are not useful in diagnosing acute tonsillitis; however, the doctor may order a CT scan to guide treatment of an **abscess** if one has developed.

Treatment

Traditional

To treat tonsillitis effectively, it is important for the doctor to know whether the tonsillitis is caused by strep throat bacteria or viruses because the treatments are different. If the child has viral tonsillitis, treatment consists largely of self–care at home: drinking plenty of warm fluids, taking nonaspirin **pain** relievers (Tylenol or Advil) to bring down the **fever**, and gargling with salt water to relieve the sore throat. It may take a week or so for the child to feel better. Antibiotics do not help in treating viral infections.

Drugs

If the doctor determines that the tonsillitis is caused by a bacterium, he or she will prescribe a course of antibiotics, most often penicillin taken by mouth, usually for 10 days. If the child has trouble swallowing, the antibiotic may be given by injection, or the doctor may also prescribe a steroid medication to bring down the throat swelling. The child should not return to school or day care for 24–48 hours after beginning antibiotic treatment, to prevent spreading the infection to others. In addition, it is important for the child to take the full course of antibiotics even though he or she may feel better in a day or two.

Surgery

The doctor may recommend **tonsillectomy** (surgical removal of the tonsils) for patients with recurrent tonsillitis. Tonsillectomy is one of the oldest surgical procedures known to Western medicine. It was first described around 50 AD by Celsus, a Roman doctor, who invented a hook for grasping tonsils. After hooking the infected tonsil with this device, Celsus removed the tissue with a sharp knife or scalpel. He then gave his patient a mixture of vinegar and herbs to stop the bleeding, cleanse the throat, and lower the risk of infection.

In the modern period, tonsillectomies are not performed nearly as often as they were in the 1950s and 1960s. The number of tonsillectomies performed each year in the United States has dropped from several million in the 1970s to approximately 600,000 in the early 2000s. Tonsillectomies are still recommended, however, to treat severe cases of recurrent tonsillitis accompanied by airway obstruction, and to reduce the risk of ear infections and other potential complications of tonsillitis.

As of 2014, surgeons in the United States generally remove tonsils with forceps and scissors after the patient has been put under general **anesthesia**. Several

WWW.BOOKBAZ.IR

new techniques for tonsillectomy have been developed that include the use of ultrasonic scalpels, lasers, and radiofrequency ablation. Radiofrequency ablation is a method that uses radiofrequency energy to shrink or destroy the tissue of the tonsils without the need for cutting.

Alternatives

Strengthening the immune system is important whether tonsillitis is caused by bacteria or viruses. Naturopaths often recommend dietary supplements of vitamin C, bioflavonoids, and beta–carotenes—found naturally in fruits and vegetables—to ease inflammation and fight infection.

A variety of herbal remedies also may be helpful in treating tonsillitis. Calendula (*Calendula officinalis*) and cleavers (*Galium aparine*) target the lymphatic system, while **echinacea** (*Echinacea* spp.) and astragalus (*Astragalus membranaceus*) stimulate the immune system. Goldenseal (*Hydrastis canadensis*), myrrh (*Commiphora molmol*), and bitter orange act as antibacterials. *Lomatium dissectum* and *Ligusticum porteri* have an antiviral action.

Some of the homeopathic medicines that may be used to treat symptoms of tonsillitis include *Belladonna*, *Phytolacca*, *Mercurius*, *Lycopodium*, *Lachesis*, *Hepar sulphuris*, *Arsenicum*, or *Rhus toxicodendron*. As with any condition, the treatment and dosage should be appropriate for the particular symptoms and age of the patient. Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

Prognosis

Most children and teenagers with tonsillitis recover without any long–term problems. In a few cases, however, the infection can spread from the tonsils to the deeper tissues of the neck or chest. If the tonsillitis is caused by streptococci, it can lead to such complications as inflammation of the kidney or **rheumatic fever**. For this reason, children with a severe sore throat and other symptoms of tonsillitis should see the doctor at once.

Tonsillectomy is the second most common operation performed on school–age children and is an extremely safe procedure. It is often done as an outpatient procedure with good results; however, the child may need to recover at home for a week or two afterward. If fever persists for more than 48 hours, or is higher than 102°F (38.9°C), the patient should be seen by a doctor. Prolonged symptoms may indicate that the patient has other upper respiratory infections, most commonly in the ears or sinuses. An abscess behind the tonsil (a peritonsillar abscess or PTA) may also occur. In rare cases, a persistent sore throat may point to more serious conditions, such as rheumatic fever or **pneumonia**.

In rare cases, the tonsils may regrow after a tonsillectomy. If the child has another episode of tonsillitis, the regrowth can be removed surgically.

Prevention

People can lower their risk of tonsillitis by washing their hands frequently, avoiding sharing drinking glasses and food utensils, covering the nose and mouth when coughing or sneezing, and avoiding close contact with others who have upper respiratory infections. Children of school age should be taught the importance of washing their hands after using the bathroom, and particularly after coughing or sneezing.

Tooth decay

Definition

Tooth decay, which is also called dental cavities or dental caries, is the destruction of the outer surface (enamel) of a tooth. Decay results from the action of bacteria that live in plaque, which is a sticky, whitish film formed by a protein in saliva (mucin) and sugary substances in the mouth. The plaque bacteria sticking to tooth enamel use the sugar and starch from food particles in the mouth to produce acid.

Description

Tooth decay is a common health problem, second in prevalence only to the **common cold**. It has been estimated that 90% of people in the United States have at least one cavity, and that 75% of people had their first cavity by the age of five. Although anyone can have a problem with tooth decay, children and senior citizens are the two groups at highest risk. Other high-risk groups include people who eat a lot of starchy and sugary foods; people living in areas without a fluoridated water supply; and people who already have numerous dental restorations (fillings and crowns).

Baby bottle tooth decay

Baby bottle tooth decay is a dental problem that frequently develops in infants that are put to bed with a bottle containing a sweet liquid. Baby bottle tooth decay is also called nursing-bottle caries and bottle-mouth syndrome. Bottles containing such liquids as milk, formula, fruit juices, sweetened drink mixes, and sugar water continuously bathe an infant's mouth with sugar during naps or at night. The bacteria in the mouth use this sugar to produce acid that destroys the child's teeth. The upper front teeth are typically the ones most severely damaged; the lower front teeth receive some protection from the tongue. Pacifiers dipped in sugar, honey, corn syrup, or other sweetened liquid also contribute to bottle-mouth syndrome. The first signs of damage are chalky white spots or lines across the teeth. As decay progresses, the damage to the child's teeth becomes obvious.

Causes and symptoms

Tooth decay requires the simultaneous presence of three factors: plaque bacteria, sugar, and a vulnerable tooth surface. Although several microorganisms found in the mouth can cause tooth decay, the primary disease agent appears to be *Streptococcus mutans*. The sugars used by the bacteria are simple sugars such as glucose, sucrose, and lactose. They are converted primarily into lactic acid. When this acid builds up on an unprotected tooth surface, it dissolves the **minerals** in the enamel, creating holes and weak spots (cavities). As the decay spreads inward into the middle layer (the dentin), the tooth becomes more sensitive to temperature and touch. When the decay reaches the center of the tooth (the pulp), the resulting inflammation (pulpitis) produces a **toothache**.

Diagnosis

Tooth decay develops at varying rates. It may be found during a routine six-month dental checkup before the patient is even aware of a problem. In other cases, the patient may experience common early symptoms, such as sensitivity to hot and cold

liquids or localized discomfort after eating very sweet foods. The dentist or dental hygienist may suspect tooth decay if a dark spot or a pit is seen during a visual examination. Front teeth may be inspected for decay by shining a light from behind the tooth. This method is called transillumination. Areas of decay, especially between the teeth, will appear as noticeable shadows when teeth are transilluminated. X rays may be taken to confirm the presence and extent of the decay. The dentist then makes the final clinical diagnosis by probing the enamel with a sharp instrument.

Tooth decay in pits and fissures may be differentiated from dark shadows in the crevices of the chewing surfaces by a dye that selectively stains parts of the tooth that have lost mineral content. A dentist can also use this dye to tell whether all tooth decay has been removed from a cavity before placing a filling.

Diagnosis in children

Damage caused by baby bottle tooth decay is often not diagnosed until the child has a severe problem, because parents seldom bring infants and toddlers in for dental check-ups. Dentists want to initially examine primary teeth between 12 and 24 months. Children still drinking from a bottle anytime after their first birthday are likely to have tooth decay.

Treatment

To treat most cases of tooth decay in adults, the dentist removes all decayed tooth structure, shapes the sides of the cavity, and fills the cavity with an appropriate material, such as silver amalgam or composite resin. The filling is put in to restore and protect the tooth. If decay has attacked the pulp, the dentist or a specialist called an endodontist may perform **root canal treatment** and cover the tooth with a crown.

In cases of baby bottle tooth decay, the dentist must assess the extent of the damage before deciding on the treatment method. If the problem is caught early, the teeth involved can be treated with fluoride, followed by changes in the infant's feeding habits and better **oral hygiene**. Primary teeth with obvious decay in the enamel that has not yet progressed to the pulp need to be protected with stainless steel crowns.

Fillings are not usually an option in small children because of the small size of their teeth and the concern of recurrent decay. When the decay has advanced to the pulp, pulling the tooth is often the treatment of choice. Loss of primary teeth at this age may hinder the young child's ability to eat and speak. It may also have bad effects on the alignment and spacing of the permanent teeth when they come in.

Prognosis

With timely diagnosis and treatment, the progression of tooth decay can be stopped without extended **pain**. If the pulp of the tooth is infected, the infection may be treated with **antibiotics** prior to root canal treatment or extraction. The longer decay goes untreated, the more destructive it becomes and the longer and more intensive the necessary treatment will be. In addition, a patient with two or more areas of tooth decay is at increased risk of developing additional cavities in the future.

Prevention

It is easier and less expensive to prevent tooth decay than to treat it. The four major prevention strategies include: proper oral hygiene; fluoride; sealants; and attention to diet.

Oral hygiene

GENERAL CARE OF THE MOUTH. The best way to prevent tooth decay is to brush the teeth at least twice a day, preferably after every meal and snack, and floss daily. Cavities develop most easily in spaces that are hard to clean. These areas include surface grooves, spaces between teeth, and the area below the gum line. Effective brushing cleans each outer tooth surface, inner tooth surface, and the horizontal chewing surfaces of the back teeth, as well as the tongue. Flossing once a day also helps prevent gum disease by removing food particles and plaque at and below the gum line, as well as between teeth. Patients should visit their dentist every six months for oral examination and professional cleaning.

MOUTH CARE IN OLDER ADULTS. Older adults who have lost teeth or had them removed still need to maintain a clean mouth. Bridges and dentures must be kept clean to prevent gum disease. Dentures should be relined and adjusted by a dentist whenever necessary to maintain proper fit. These adjustments help to keep the gums from becoming red, swollen, and tender.

MOUTH CARE IN CHILDREN. Parents can easily prevent baby bottle tooth decay by not allowing a child to fall asleep with a bottle containing sweetened liquids. Bottles should be filled only with plain, unsweetened water. The child should be introduced to drinking from a cup around six months of age and weaned from bottles by twelve months. If an infant seems to need oral comfort between feedings, a pacifier specially designed for the mouth may be used. Pacifiers, however, should never be dipped in honey, corn syrup, or other sweet liquids. After the eruption of the first tooth, parents should begin routinely wiping the infant's teeth and gums with a moist piece of gauze or a soft cloth, especially right before bedtime. Parents may begin brushing a child's teeth with a small, soft toothbrush at about two years of age, when most of the primary teeth have come in. They should apply only a very small amount (the size of a pea) of toothpaste containing fluoride. Too much fluoride may cause spotting (fluorosis) of the tooth enamel. As the child grows, he or she will learn to handle the toothbrush, but parents should control the application of toothpaste and do the followup brushing until the child is about seven years old.

Fluoride application

Fluoride is a natural substance that slows the destruction of enamel and helps to repair minor tooth decay damage by remineralizing tooth structure. Toothpaste, mouthwash, fluoridated public drinking water, and vitamin supplements are all possible sources of fluoride. Children living in areas without fluoridated water should receive 0.5 mg/day of fluoride (0.25 mg/day if using a toothpaste containing fluoride) from 3–5 years of age, and 1 mg/day from 6–12 years.

While fluoride is important for protecting children's developing teeth, it is also of benefit to older adults with receding gums. It helps to protect their newly exposed tooth surfaces from decay. Older adults can be treated by a dentist with a fluoride solution that is painted onto selected portions of the teeth or poured into a fitted tray and held against all the teeth.

Sealants

Because fluoride is most beneficial on the smooth surfaces of teeth, sealants were developed to protect the irregular surfaces of teeth. A sealant is a thin plastic coating that is painted over the grooves of chewing surfaces to prevent food and plaque from being trapped there. Sealant treatment is painless because no part of the tooth is removed, although the tooth surface is etched with acid so that the plastic will adhere to the rough surface. Sealants are usually clear or tooth-colored, making them less noticeable than silver fillings. They cost less than fillings and

can last up to 10 years, although they should be checked for wear at every dental visit. Children should get sealants on their first permanent "6-year" molars, which come in between the ages of five and seven, and on the second permanent "12-year" molars, which come in between the ages of 11 and 14. Sealants should be applied to the teeth shortly after they erupt, before decay can set in. Although sealants have been used in the United States for about 25 years, one survey by the National Institute of Dental Research reported that fewer than 8% of American children have them.

Diet

The risk of tooth decay can be lowered by choosing foods wisely and eating less often. Foods high in sugar and starch, especially when eaten between meals, increase the risk of cavities. The bacteria in the mouth use sugar and starch to produce the acid that destroys the enamel. The damage increases with more frequent eating and longer periods of eating. For better dental health, people should eat a variety of foods, limit the number of snacks, avoid sticky and overly sweetened foods, and brush often after eating.

Drinking water is also beneficial for rinsing food particles from the mouth. Children can be taught to "swish and swallow" if they are unable to brush after lunch at school. Similarly, saliva stimulated during eating makes it more difficult for food and bacteria to stick to tooth surfaces. Saliva also appears to have a buffering effect on the acid produced by the plaque bacteria and to act as a remineralizing agent. Older patients should be made aware that some prescription medications may decrease salivary flow. Less saliva tends to increase the activity of plaque bacteria and encourage further tooth decay. Chewing sugarless gum increases salivation and helps to lower the risk of tooth decay.

Tooth extraction

Definition

Tooth extraction is the removal of a tooth from its socket in the bone.

Purpose

Extraction is performed for positional, structural, or economic reasons. Teeth are often removed because they are impacted. Teeth become impacted when they are prevented from growing into their normal position in the mouth by gum tissue, bone, or other teeth. Impaction is a common reason for the extraction of wisdom teeth. Extraction is the only known method that will prevent further problems with impaction.

Teeth may also be extracted to make more room in the mouth prior to straightening the remaining teeth (orthodontic treatment), or because they are so badly

positioned that straightening is impossible. Extraction may be used to remove teeth that are so badly decayed or broken that they cannot be restored. In addition, some patients choose extraction as a less expensive alternative to filling or placing a crown on a severely decayed tooth.

Demographics

Exact statistics concerning tooth extraction are not available. Experts estimate that over 20 million teeth are extracted each year in the United States. Many of these are performed in conjunction with orthodontic procedures. Some extractions are due to **tooth decay**.

Description

Teeth are most often extracted by maxillofacial or oral surgeons. Occasionally, a general dentist will extract a tooth. Teeth are most commonly removed in an outpatient facility adjacent to a hospital under general anesthesia.

Tooth extraction can be performed with local **anesthesia** if the tooth is exposed and appears to be easily removable in one piece. The dentist or oral surgeon uses an instrument called an elevator to luxate, or loosen, the tooth; widen the space in the underlying bone; and break the tiny elastic fibers that attach the tooth to the bone. Once the tooth is dislocated from the bone, it can be lifted and removed with forceps.

If the extraction is likely to be difficult, a general dentist may refer the patient to an oral surgeon. Oral surgeons are specialists who are trained to administer nitrous oxide (laughing gas), an intravenous sedative, or a general anesthetic to relieve **pain**. Extracting an **impacted tooth** or a tooth with curved roots typically requires cutting through gum tissue to expose the tooth. It may also require removing portions of bone to free the tooth. Some teeth must be cut and removed in sections. The extraction site may or may not require one or more stitches (sutures) to close the incision.

Precautions

In some situations, tooth extractions may be temporarily postponed:

- Infection that has progressed from the tooth into the bone complicates administering anesthesia. Infections must be treated with antibiotics before extraction.
- Patients taking blood thinners, such as warfarin (Coumadin) and aspirin, should stop using these medications for three days prior to extraction.
- People who have had certain medical procedures—heart valve replacement, open heart surgery, prosthetic joint replacement, or placement of a medical shunt—in the past six months may be given antibiotics to reduce the risk of bacterial infection spreading from the mouth to other parts of the body.

Preparation

Before extracting a tooth, the dentist will take the patient's medical history, noting **allergies** and other prescription medications that the patient is taking. A dental history is also recorded. Particular attention is given to previous extractions and reactions to anesthetics. The dentist may then prescribe **antibiotics** or recommend stopping certain medications prior to the extraction. The tooth is x rayed to determine its full shape and position, especially if it is impacted.

Patients scheduled for deep anesthesia should wear loose clothing with sleeves that are easily rolled up to allow the dentist to place an intravenous line. They should not eat or drink anything for at least six hours before the procedure. Arrangements should be made for a friend or relative to drive them home after the surgery.

Aftercare

An important aspect of aftercare is encouraging a clot to form at the extraction site. The patient should put pressure on the area by biting gently on a roll or wad of gauze for several hours after surgery. Once the clot is formed, it should not be disturbed. The patient

KEY TERMS

Dry socket—A painful condition following tooth extraction in which a blood clot does not properly fill the empty socket. Dry socket leaves the underlying bone exposed to air and food particles.

Extraction site—The empty tooth socket following removal of a tooth.

Impacted tooth—A tooth that is growing against another tooth, bone, or soft tissue.

Luxate—To loosen or dislocate a tooth from its socket.

Nitrous oxide—A colorless, sweet-smelling gas used by dentists for mild anesthesia. It is sometimes called laughing gas because it makes some people feel giddy or silly.

Oral surgeon—A dentist who specializes in surgical procedures of the mouth, including extractions.

Orthodontic treatment—The process of realigning and straightening teeth to correct their appearance and function.

should not rinse, spit, drink with a straw, or smoke for at least 24 hours after the extraction and preferably longer. He or she should also avoid vigorous **exercise** for the first three to five days after the extraction.

For the first two days after the procedure, the patient should drink liquids without using a straw and eat soft foods. Any chewing must be done on the side away from the extraction site. Hard or sticky foods should be avoided. The mouth may be gently cleaned with a toothbrush, but the extraction area should not be scrubbed.

Wrapped ice packs can be applied to reduce facial swelling. Swelling is a normal part of the healing process; it is most noticeable in the first 48–72 hours after surgery. As the swelling subsides, the patient's jaw muscles may feel stiff. Moist heat and gentle exercise will restore normal jaw movement. The dentist or oral surgeon may prescribe medications to relieve postoperative pain.

Risks

Potential complications of tooth extraction include postoperative infection, temporary numbness from nerve irritation, jaw fracture, and jaw joint pain. An additional complication is called dry socket. When a blood clot does not properly form in the empty tooth socket, the bone beneath the socket is exposed to air and contamination by food particles; as a result, the extraction site heals more slowly than is normal or desirable.

Results

The wound usually closes in about two weeks after a tooth extraction, but it takes three to six months for the bone and soft tissue to be restructured. Such complications as infection or dry socket may prolong the healing process.

Morbidity and mortality rates

Mortality from tooth extraction is very rare. Complications include a brief period of pain and swelling; post-extraction infections; and migration of adjacent teeth into the empty space created by an extraction. Most people experience some pain and swelling after having a tooth extracted. With the exception of removing wisdom teeth, migration into the empty space is common. Braces or orthodontic appliances usually control this problem.

Alternatives

Alternatives to tooth extraction depend on the reason for the extraction. Postponing or canceling an extraction to correct tooth crowding will cause **malocclusion** and an undesirable appearance. Not removing an impacted wisdom tooth may cause eventual misalignment, although it may have no impact. Not removing a decayed or abscessed tooth may lead to septicemia and other complications.

Tooth replacements and restorations

Definition

A tooth restoration is any artificial substance or structure that replaces missing teeth or part of a tooth in order to protect the mouth's ability to eat, chew, and speak. Restorations include fillings, inlays, crowns, bridges, partial and complete dentures, and **dental implants**.

Purpose

Restorations have somewhat different purposes depending on their extensiveness. Fillings, inlays, and crowns are intended to repair damage to individual teeth. They replace tooth structure lost by decay or injury, protect the part of the tooth that remains, and restore the tooth's shape and function. Bridges, dentures, and implants are intended to protect the shape and function of the mouth as a whole.

Precautions

Some patients are allergic to the medications used for local **anesthesia** in dental restorations. In addition, many people in the general population are afraid of dental work. Most dentists in present-day practice can help patients with this specific fear.

Description

Fillings

Fillings are restorations that are done to repair damage caused by **tooth decay** (dental caries). Tooth decay occurs when microorganisms in the mouth convert sugar from food to acid, which attacks the tooth. The acid forms cavities that start in the hard outer surface of the tooth (the enamel) and may extend inward to the pulp, which contains the tooth's nerves and blood vessels. Left untreated, tooth decay may lead to inflammation and infection that may cause **toothache** and perhaps more serious complications.

To stop the decay process, the dentist removes the decayed portion of the tooth using a high-speed drill or an air abrasion system, shapes the cavity walls, and replaces the tooth structure with a filling of silver amalgam, composite resin, or gold. The filling is placed in the cavity as a liquid or soft solid. It sets within a few minutes and continues to harden over the next several hours. Silver amalgam is commonly used to fill cavities on the biting surfaces of the back teeth, because it is strong enough to withstand the tremendous pressures exerted by grinding and chewing. Composite resin is typically used to fill cavities in front teeth and any other teeth that are visible when the patient smiles, because its color can be matched to the tooth surface. Gold as a filling material is far less common, but is being increasingly used. Although it is more expensive and less easily applied, it does not trigger the sensitivity reactions that some patients have to silver amalgam.

Inlays

An inlay resembles a filling in that it fills the space remaining after the decayed portion of a tooth has been removed. The difference is that an inlay is shaped outside the patient's mouth and then cemented into place. After the decay is removed and the cavity walls are shaped, the dentist makes a wax pattern of the

WWW.BOOKBAZ.IR

space. A mold is cast from the wax pattern. An inlay, usually of gold, is made from this mold and sealed into the tooth with dental cement.

Crowns

The crown of a tooth is the portion that is covered by enamel. A restorative crown replaces this outer part to protect the tooth. This protection becomes necessary when a tooth cracks or has its entire structure weakened by decay. As with a filling or inlay, the dentist first removes the decayed portion of the tooth. The tooth is then prepared for a crown. It may be tapered on the outside edges to a peg, reinforced with a cast metal core, or rebuilt with both a cast metal core and a post. A wax impression of the prepared tooth and the teeth next to it is made. The new crown is made to fit this mold. The crown may be made of gold or stainless steel alone, metal with a veneer of tooth-colored porcelain or resin, or of porcelain or resin alone. The finished crown is then placed over the prepared tooth, adjusted, and cemented into place.

Bridges

Bridges are a type of restoration that is done when one or more permanent teeth are lost or pulled. The resulting gap must be filled in to prevent the remaining teeth from shifting. If the other teeth shift, they will affect the patient's bite (occlusion), which sometimes produces **pain** in the jaw joint. As the teeth move and become crooked, they also become more difficult to keep clean. The risk of tooth decay and gum disease increases, increasing the likelihood that additional teeth will be lost. A bridge is inserted to prevent this risk. Bridges are nonremovable appliances of one or more artificial teeth (pontics) anchored by crowns on the adjacent teeth (abutment teeth). The abutment teeth carry the pressure when the patient chews food.

Partial dentures

A partial denture is similar to a bridge in that it fills a gap left by missing teeth with artificial teeth on a metal frame. A partial denture is removable, however. It attaches to a crown on the abutment tooth with a metal clasp or precision attachment. A partial denture is primarily used at the end of a row of natural teeth, where there is only one abutment tooth. The pressure exerted by chewing is shared by this abutment and the soft tissues of the gum ridge beneath the appliance.

Complete dentures

Complete dentures may be worn when all of the top or bottom teeth have been lost. A complete denture consists of artificial teeth mounted in a plastic base molded to fit the remaining oral anatomy. It may or may not be held in place with a denture adhesive.

Implants

Dental implants are a means of securing crowns, bridges, and dentures in the mouth. A hard plastic or metal fixture is implanted through the soft tissue into the bone. Over time, the bone grows around this fixture, firmly anchoring it. The exposed end of this fixture is covered with a crown and may serve as a stable abutment for a bridge or denture.

Preparation

Before a restoration is placed in the mouth, the dentist removes all traces of decay and shapes the remaining tooth structure for the restoration. Fillings are the only restoration created within the tooth itself—the others are made up in a laboratory using a model of the tooth structure. Thus, a filling may be placed in a single dental visit, while the other restorations usually take several appointments. Temporary crowns and dentures are put in place after the tooth is shaped until the permanent restoration is delivered by the laboratory.

Aftercare

Fillings

Fillings need time to harden for several hours after being placed, so the patient should chew food on the opposite side of the mouth for the first day.

Dentures

A partial or complete denture may take several weeks of getting used to. Inserting and removing the denture will take practice. Speaking clearly may be difficult at first—the patient may find it helpful to read out loud for practice. Eating may also feel awkward. The patient should begin by eating small pieces of soft foods. Very hard or sticky foods should be avoided.

Patients with dentures must work on good **oral hygiene**. Specialty brushes and floss threaders may be used to remove plaque and food from around crowns and bridges. Dentures should be removed and brushed daily with a specially designed brush and a denture cleaner or other mild soap.

KEY TERMS

Abutment tooth—A crowned tooth that stabilizes a bridge or partial denture.

Bridge—An appliance of one or more artificial teeth anchored by crowns on the adjacent teeth.

Complete denture—A full set of upper or lower teeth, mounted in a plastic base. Dentures are also called false teeth.

Crown—A protective shell that fits over the tooth.

Dental caries—A disease of the teeth in which microorganisms convert sugar in the mouth to acid that erodes the tooth.

Enamel—The hard outermost surface of a tooth.

Filling—Dental material that occupies the space remaining within a tooth after the decayed portion has been removed.

Implant—A fixture with one end implanted into the bone and the other end covered with a crown, often to serve as a stable abutment for a bridge or denture.

Inlay—A filling that is made outside of the tooth and then cemented into place.

Occlusion—The way upper and lower teeth fit together during biting and chewing.

Partial denture—A removable bridge that usually clasps onto only one abutment.

Pontic—An artificial tooth.

Pulp—The soft innermost layer of a tooth that contains its blood vessels and nerves.

The patient should see the dentist for an adjustment if there is any discomfort or irritation resulting from a restoration. Otherwise, the patient should see the dentist at least twice a year for an oral examination.

Risks

Restoration procedures typically require local anesthesia. Some people may have allergic reactions to the medication. A very small number of people are allergic to one or more of the metals used in a **dental restoration**. In most cases, the dentist can use another material.

Results

A well-made restoration should feel comfortable and last a relatively long time with proper care. Artificial dental restorations only approximate the original tooth, however. A complete denture will never feel as comfortable or work as well as natural teeth. It is better to prevent the need for restorative dental work than to replace teeth. Restorations are expensive, may require many appointments, and still need careful cleaning and attention.

Tooth replantation

Definition

Tooth replantation is the reinsertion and splinting of a tooth that has been avulsed (knocked or torn out) of its socket.

Purpose

Teeth are replanted to prevent permanent loss of the tooth, and to restore the landscape of the mouth so that the patient can eat and speak normally.

Demographics

According to the National Center for Health Statistics, about five million teeth are accidentally avulsed in the United States each year. Most teeth that are replanted are lost through **trauma**, usually falls and other types of accidents. The most common trauma resulting in tooth avulsion are sports accidents that result in falls or blows to the head. The mandatory use of mouth guards, which are plastic devices that protect the upper teeth, has prevented approximately 200,000 oral injuries each year in football alone. The American Dental Association recommends the use of mouth guards for any sport that involves speed, contact, or the potential for falls. These categories include not only contact sports like football, wrestling, and boxing, but also gymnastics, baseball, hockey, bicycling, skateboarding, and skiing. Without a mouth guard, a person is 60 times more likely to experience **dental trauma** if he or she participates in these sports.

WWW.BOOKBAZ.IR

Other common causes of trauma to the mouth resulting in avulsed teeth include motor vehicle accidents, criminal assaults, and fist fights. Domestic violence is the most common cause of avulsed teeth in women over the age of 21.

Description

Tooth replantations are performed by general dentists, endodontists, and oral surgeons, usually as office or outpatient procedures. In some cases, the patient may be treated in the emergency room of a hospital.

In most cases, only permanent teeth are replanted. Primary teeth (baby teeth) do not usually have long enough roots for successful replantation. The only exception may be the canine teeth, which have longer roots and a better chance of staying in place. In some cases, the dentist may choose to replant a child's primary tooth because there is risk to the permanent tooth that has not yet emerged.

To replant a tooth, the dentist or oral surgeon will first administer a local anesthetic to numb the patient's gums. He or she will then reinsert the avulsed tooth in its socket and anchor it within the mouth by installing a splint made of wire and composite resin. Some dentists remove the root canal nerve of the tooth and replace it with a plastic material before reinserting the tooth. The splint holds the tooth in place for two to six weeks. At that time, the splint can be removed and the tooth examined for stability.

Preparation

When a tooth is dislodged, it is critical to recover the tooth, preserve it under proper conditions, and get the patient to a dentist immediately. The tooth should be handled carefully; it should be picked up or touched by its crown (the top part of the tooth), not by its root. The tooth should be rinsed and kept moist, but not cleaned or brushed. The use of toothpaste, soap, mouthwash, or other chemicals can remove the fibroblasts clinging to the root of the tooth. Fibroblasts are connective tissue cells that act as a glue between teeth and the underlying bone.

The avulsed tooth can be placed in milk or a special Save-a-Tooth® kit, which is a tooth-preserving cup that contains a medium for preserving the fibroblasts around the tooth. The tooth and the patient should go to the dentist within 30 minutes of the accident since fibroblasts begin to die within that time. Rapid treatment improves the chances for successful replantation. In some cases, artificial fibroblasts can be substituted for the patient's own connective tissue cells.

KEY TERMS

Avulsion—A ripping out or tearing away of a tooth or other body part.

Canine tooth—In humans, the tooth located in the mouth next to the second incisor. The canine tooth has a pointed crown and the longest root of all the teeth.

Crown—The top part of the tooth.

Endodontist—A dentist who specializes in the diagnosis and treatment of disorders affecting the pulp of a tooth, the root of the tooth, or the tissues surrounding the root. Some patients with avulsed teeth may be treated by an endodontist.

Eruption—The emergence of a tooth through the gum tissue.

Fibroblasts—Connective tissue cells that help to hold the teeth in their sockets in the jawbone.

Mouth guard—A plastic device that protects the upper teeth from injury during athletic events.

Primary teeth—A child's first set of teeth, sometimes called baby teeth.

If the tooth is a primary tooth, it should be rinsed and kept moist. The dentist should be consulted to determine whether the tooth should be replanted by examining the gums and the emergent tooth. The dentist will take a set of x rays to determine how soon the permanent tooth is likely to emerge. Sometimes an artificial spacer is placed where the primary tooth was lost until the permanent tooth comes in.

Any injury to the gum is treated before the tooth is replanted. The dentist may give the patient an antibiotic medication to reduce the risk of infection. Cold compresses can reduce swelling. Stitches may be necessary if the gum is lacerated. The dentist may also take x rays of the mouth to see if there are other injuries to the jawbone or nearby teeth.

Aftercare

The patient may take **aspirin** or **acetaminophen** for **pain**. **Antibiotics** may also be given for infection. The patient should avoid rinsing the mouth, spitting, or **smoking** for the first 24 hours after surgery. He or she should limit food to a soft diet for the next few days.

Beginning 24 hours after surgery, the patient should rinse the mouth gently with a solution of salt

and lukewarm water every one to two hours. The salt helps to reduce swelling in the tissues around the tooth.

Any kind of traumatic injury always carries the risk of infection. Patients with **heart disease** or disorders of the immune system should be monitored following tooth replantation. Dentists recommend consulting a physician within 48 hours of the dental surgery to determine the risk of **tetanus**, particularly if the patient has not received a tetanus booster within the past five years.

Adults with replanted teeth should have periodic checkups. According to the American Association of Endodontists, it takes 2–3 years after replantation before the dentist can fully evaluate the outcome of treatment.

Risks

In addition to infection, tooth replantation carries the risks of excessive bleeding and rejection of the tooth. Rejection is a rare complication. An additional risk is that the root of the tooth may become fused to the underlying bone.

Results

Most permanent tooth replantations are successful when the patient acts quickly (within two hours). If the tooth is rejected, the dentist may attach the tooth to the bone with tissue glue. The rate of complications varies according to the circumstances of the injury, the patient's age, and his or her general health. A history of smoking increases the risk of rejection of the tooth, as well as infection.

Alternatives

There are no effective medical alternatives to oral surgery for replanting an avulsed tooth. Over-the-counter **analgesics** (pain relievers), prescription antibiotics, and some herbal preparations may be useful in relieving pain, reducing swelling, or preventing infection.

Herbal preparations that have been found useful as mouthwashes following oral surgery include calendula (*Calendula officinalis*) and clove (*Eugenia caryophyllata*).

Toothache

Definition

A toothache is any **pain** or soreness within or around a tooth, indicating inflammation and possible infection.

Demographics

Serious toothaches and oral health problems are much less common today than ever before in history. The widespread availability of preventive dentistry and toothbrushes, toothpaste, and other oral care items has greatly improved oral health. However, most people experience some form of tooth pain at least once in their lives. Toothaches may occur more frequently in populations without regular access to dental care, such as low-income individuals. Toothaches also are more common in the elderly and individuals with certain diseases and conditions that make **tooth decay** more likely.

WWW.BOOKBAZ.IR

Description

A toothache may be either a sharp pain or a dull ache. The tooth may be sensitive to pressure, heat, cold, or sweets. In cases of severe pain, identifying the problem tooth can be difficult. Any patient with a toothache should see a dentist at once for diagnosis and treatment. Most toothaches get worse if not treated.

Causes and symptoms

Toothaches may result from many causes:

- tooth decay (dental caries)
- inflammation of the tooth pulp (pulpitis)
- abscess
- gum disease, including periodontitis
- loose or broken filling
- cracked or impacted tooth
- exposed tooth root
- food wedged between teeth or trapped below the gum line
- tooth nerve irritated by clenching or grinding of teeth (bruxism)
- pressure from congested sinuses
- traumatic injury

Diagnosis

Diagnosis includes identifying the location of the toothache, as well as the cause. The dentist begins by asking the patient specific questions about the toothache, including the types of foods that make the pain worse, whether the tooth is sensitive to temperature or biting, and whether the pain is worse at night. The dentist then examines the patient's mouth for signs of swelling, redness, and obvious tooth damage. The presence of pus indicates an **abscess** or gum disease. The dentist may flush the sore area with warm water to dislodge any food particles and to test for sensitivity to heat. The dentist may then dry the area with gauze to determine sensitivity to touch and pressure. The dentist may probe tooth crevices and the edges of fillings with a sharp instrument, looking for areas of tooth decay. Finally, the dentist may take x rays, looking for evidence of decay between teeth, a cracked or **impacted tooth**, or a disorder of the underlying bone.

Treatment

Emergency self-care

Toothaches should be professionally treated by a dentist. Some methods of self-treatment, however, may help manage the pain until professional care is available. Common home treatments include:

- rinsing with warm salt water
- using dental floss to remove any food particles
- taking aspirin or acetaminophen (Tylenol) to relieve pain; the drug should be swallowed and never placed directly on the aching tooth or gum
- applying a cold compress against the outside of the cheek; heat should not be used as it can increase the likelihood that the infection will spread
- using clove oil (*Syzygium aromaticum*) to numb the gums; the oil may be rubbed directly on the sore area or used to soak a small piece of cotton and applied to the sore tooth

Traditional

Treatment will depend on the underlying cause of the toothache. If the pain is due to tooth decay, the dentist will remove the decayed area and restore the tooth with a filling of silver amalgam or composite resin. Loose or broken fillings are removed, new decay cleaned out, and a new filling is placed. If the pulp of the tooth is damaged, root canal therapy may be

KEY TERMS

Abscess—A hole in the tooth or gum tissue filled with pus as the result of infection.

Bruxism—Habitual clenching and grinding of the teeth because of stress. The behavior usually occurs during sleep.

Cavity—A hole or weak spot in the tooth surface caused by decay.

Dental caries—A disease of the teeth in which microorganisms convert sugar in the mouth to acid, which then erodes the tooth.

Enamel—The hard outermost surface of a tooth.

Endodontist—A dentist who specializes in diagnosing and treating diseases of the pulp and other inner parts of the tooth.

Impacted tooth—A tooth that is growing against another tooth, bone, or soft tissue.

Periodontitis—A gum disease that destroys the structures supporting the teeth, including bone.

Pulp—The soft innermost part of a tooth, containing blood vessels and nerves.

Pulpitis—Inflammation of the pulp of a tooth that involves the blood vessels and nerves.

required. During a root canal the dentist or a specialist called an endodontist removes the decayed pulp, fills the space left behind with a soothing paste, and covers the tooth with a crown to protect and seal it. If the damage cannot be treated by these methods, or if the tooth is impacted, the tooth must be extracted.

Alternatives

Toothaches caused by infection or tooth decay must be treated by a dentist. Several alternative therapies may be helpful for pain relief until dental treatment is available. Clove oil (*Syzygium aromaticum*) may be rubbed on sensitive gums to numb them or added to a small cotton pellet that is then placed into or over a hole in the tooth. The herb corydalis (*Corydalis yanhusuo*) may also help relieve toothache pain. Pain also may be reduced using **acupressure**, **acupuncture**, or **reiki**. Acupuncture should be done only by a licensed practitioner.

Prognosis

Prompt dental treatment provides a positive outcome for toothache. In the absence of active infection, fillings, root canal treatments, or extractions may be performed with minimal discomfort to the patient. When a toothache is left untreated, a severe infection may develop and spread to the sinuses or jawbone, and eventually cause blood **poisoning**.

Prevention

Maintaining proper **oral hygiene** is the key to preventing toothaches. The best way to prevent tooth decay is to brush at least twice a day, preferably after every meal and snack. Flossing once a day also helps prevent gum disease by removing food particles and bacteria at and below the gum line, as well as between teeth. Visiting the dentist at least every six months for oral examinations and professional cleaning can help prevent a variety of oral health problems that can lead to toothache.

Topical anesthesia

Definition

Topical **anesthesia** is a condition of temporary numbness caused by applying a substance directly to a surface of the body. Loss of feeling occurs in the specific areas touched by the anesthetic substance.

Purpose

Topical anesthesia typically either relieves existing **pain** from a body surface or prevents pain during medical examinations or procedures. Body surfaces include both skin and mucous membranes, which are the moist linings of areas such as the inside of the mouth or nose. Occasionally, use of a topical anesthetic may help clarify whether a patient's pain comes from a body surface, which the substance is able to touch, or from deeper structures beyond the reach of the substance. A mucous membrane, an area of skin, or areas just beneath the skin's surface temporarily loses feeling during topical anesthesia.

Precautions

Topical anesthetic medications must be selected carefully and used in proper amounts in order to prevent harmful reactions. For instance, some topical drugs should be used only on intact skin to avoid rapid absorption into the body. Therefore, it is important to choose the right type and dosage of anesthetic for each specific purpose.

WWW.BOOKBAZ.IR

Description

Most drugs in the early 2000s used to cause topical anesthesia have at least some chemical similarity to cocaine, which was recognized as a topical anesthetic in the early 1900s. These drugs work by blocking nerve impulses that carry pain messages to the brain. Commonly used, twenty-first-century drugs include benzocaine, lidocaine, prilocaine, and tetracaine, These drugs come in several application forms, such as cream, jelly, ointment, solution, and spray, are available in varying strengths, and may be used alone or in combinations.

One common use for topical anesthetics is to relieve pain from problems such as sores in the mouth, skin scrapes, and **hemorrhoids**. A person typically applies a cream or jelly to the affected area. Numbness begins within a few minutes, and the anesthetic effect may last an hour or more. Repeated applications are often necessary.

The other broad category of use for topical anesthetics is to prevent pain from medical examinations or procedures on areas such as the eye, nose, throat, urethra, rectum, or skin. For example, even a single drop of anesthetic may allow examination of a painfully irritated eye or removal of a speck of dirt from the eye surface. Careful inspection of a nostril or insertion of a urinary drainage tube into the urethra may be difficult or impossible without the use of topical anesthetic spray or jelly beforehand.

Many uses of topical anesthetics involve application to the skin. Physicians and patients have long hoped for a way to numb an area of skin without having to use a needle to inject anesthetic. Original topical anesthetics were not effective in this way. A newer drug preparation called eutectic mixture of local anesthetics (EMLA, lidocaine 2.5%, and prilocaine 2.5%) can be used as a cream on intact skin. When applied for about 60 minutes, EMLA numbs the skin and penetrates as far as 5 mm below the surface. EMLA may help patients by decreasing the pain of needle pricks or simple skin procedures, such as repair of small lacerations. The main drawback to EMLA is that it takes so long for the anesthetic effect to begin, thus reducing its usefulness in settings such as the emergency rooms. Other drug combinations such as tetracaine, epinephrine (adrenaline), and cocaine (TAC), or lidocaine, epinephrine, and tetracaine (LET) have their own advantages and disadvantages.

The application of ice to a body area is a primitive method of producing topical anesthesia. Chemicals such as ethyl chloride can be sprayed onto intact skin to produce a momentary freezing and numbing effect.

KEY TERMS

Anesthetic—Not having sensation; related to the loss of sensation; or, a substance that produces loss of sensation.

EMLA—Eutectic mixture of local anesthetics, a drug combination for use on intact skin.

LET—A topical anesthetic mixture containing lidocaine, epinephrine, and tetracaine.

Mucous membranes—Moist linings of body surfaces such as the inside of the mouth or nose.

Numbness—Loss of feeling or sensation.

TAC—A topical anesthetic mixture containing tetracaine, epinephrine (adrenaline), and cocaine.

Topical—For use directly on a body surface.

Covering the ointment with plastic wrap increases the absorption of the ointment through the skin. The use of plastic wrap, or other occlusive dressings, is the standard means of applying EMLA cream. Other techniques include using gentle heat or electric current to help the drugs penetrate intact skin.

Risks

Overall, topical anesthesia tends to be very safe. Minor problems might include discoloration of the skin at the application site or an uncomfortable feeling of numbness that lasts longer than expected. Repeated use of a topical anesthetic on a damaged eye surface may interfere with the normal healing process. Rarely, too much of the drug may be absorbed into the body in a short time and cause a reaction such as seizure or rapid heartbeat. Death related to topical anesthesia is extremely rare.

Results

Successful use of a topical anesthetic produces temporary loss of sensation in the area where it is applied.

TORCH test

Definition

The TORCH test, which is sometimes called the TORCH panel, belongs to a category of blood tests called infectious-disease antibody titer tests. This type of blood test measures the presence of antibodies (protein molecules produced by the human immune system in response to a specific disease agent) and their level of concentration in the blood. The name of the test comes from the initial letters of the five disease categories. The TORCH test measures the levels of an infant's antibodies against five groups of chronic infections: *t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus (CMV), and *h*erpes simplex virus (HSV). The "other infections" usually include **syphilis**, **hepatitis B**, coxsackie virus, **Epstein-Barr virus**, varicella-zoster virus, and human parvovirus.

Since the TORCH test is a screening or first-level test, the pediatrician may order tests of other body fluids or tissues to confirm the diagnosis of a specific infection. In the case of **toxoplasmosis**, **rubella**, and syphilis, cerebrospinal fluid may be obtained from the infant through a spinal tap in order to confirm the diagnosis. In the case of CMV, the diagnosis is confirmed by culturing the virus in a sample of the infant's urine. In HSV infections, tissue culture is the best method to confirm the diagnosis.

Purpose

The five categories of organisms whose antibodies are measured by the TORCH test are grouped together because they can cause a cluster of symptomatic **birth defects** in newborns. This group of defects is sometimes called the TORCH syndrome. A newborn baby with these symptoms will be given a TORCH test to see if any of the five types of infection are involved.

The symptoms of the TORCH syndrome include:

- Small size in proportion to length of the mother's pregnancy at time of delivery. Infants who are smaller than would be expected (below the tenth percentile) are referred to as small-for-gestational-age, or SGA.
- Enlarged liver and spleen
- Low level of platelets in the blood
- Skin rash. The type of skin rash associated with the TORCH syndrome is usually reddish-purple or brown and is caused by the leakage of blood from broken capillaries into the baby's skin.
- Involvement of the central nervous system. These defects can include encephalitis, calcium deposits in the brain tissue, and seizures.
- Jaundice. The yellowish discoloration of the skin and whites of the eyes due to liver disease.

In addition to these symptoms, each of the TORCH infections has its own characteristic symptom cluster in newborns:

Toxoplasmosis

Toxoplasmosis is caused by *Toxoplasma gondii*, a parasite that the mother can acquire from handling infected cats, drinking unpasteurized milk, or eating contaminated meat. The infection is carried to the infant through the mother's placenta, and can cause infections of the eyes or central nervous system. The organism can invade brain or muscle tissue and form tissue cysts. The later in **pregnancy** that the mother is infected, the higher the probability that the fetus will be infected. On the other hand, toxoplasmosis early in pregnancy is more likely to cause a **miscarriage** or serious birth defects. The incidence of toxoplasmosis in newborns is one in 1,000 live births.

Other (syphilis)

Syphilis is caused by a spirochete (spiral- or coil-shaped bacterium), *Treponema pallidum*. It is transmitted in the adult population by sexual intercourse. About 2–5% of children born to mothers diagnosed with syphilis will have the disease at birth. Syphilis was added to the TORCH panel because of a rapid increase in reported cases since 1990. It is also a potentially life-threatening infection for the fetus. Syphilis can cause early delivery, miscarriage, or **stillbirth**. The mortality rate in infants infected with syphilis is about 54%.

Rubella

Rubella is a virus that has a seasonal pattern, with epidemics most likely in the spring. Between 0.1–2%

WWW.BOOKBAZ.IR

of newborns will be infected with rubella. The rate of fetal infection varies according to the timing of the mother's infection during pregnancy. Birth defects, however, are most likely (85%) in infants infected during the first eight weeks of pregnancy. Infants born with rubella may already show signs of **heart disease**, retarded growth, **hearing loss**, blood disorders, vision problems, or **pneumonia**. They may also develop problems later in childhood, including **autism**, hearing loss, brain syndromes, immune system disorders, or thyroid disease.

Cytomegalovirus (CMV)

Cytomegalovirus belongs to the herpesvirus group of infections. It can be transmitted through body secretions, as well as by sexual contact; some newborns acquire CMV through the mother's breast milk. In adults, it produces symptoms resembling those of mononucleosis. About 1–2.2% of newborns in the United States are infected with CMV. Of this group, 10% will have measurable symptoms. The mortality rate for these symptomatic newborns is 20–30%. Surviving infants with CMV may have hearing problems (15%) or intellectual disabilities (30%). Newborns that acquire CMV during the birth process or shortly after birth may develop pneumonia, hepatitis, or various blood disorders.

Herpes simplex virus (HSV)

Herpesvirus infections are among the most common viral infections in humans. They are spread by oral, as well as genital, contact. It is estimated that between 1 in 1,000 and 1 in 5,000 infants are born with HSV infections. About 80% of these infections are acquired during the birth process itself; the virus enters the infant through its eyes, skin, mouth, and upper respiratory tract. Of infants born with HSV infection, about 20% will have localized infections of the eyes, mouth, or skin. About 50% of infected infants will develop disease spread throughout the body (disseminated) 9–11 days after birth. Disseminated herpes infections attack the liver and adrenal glands, as well as other body organs. Without treatment, the mortality rate is 80%. Even with antiviral medication, the mortality rate is still 15–20%, with 40–55% of the survivors having long-term damage to the central nervous system. It is critical for the doctor to diagnose HSV infection in the newborn as soon as possible, for effective treatment.

Description

The TORCH panel requires a sample of the infant's blood. Samples from infants are usually obtained by the heelstick procedure when only a small quantity of blood is needed. The baby's foot is wrapped in a warm cloth for five minutes, to make the blood flow more easily. The foot is then wiped with an alcohol swab and a lancet is used to stick the baby's heel on one side. It is important to avoid the center of the heel, in order to prevent an inflammation of the bone.

KEY TERMS

Antibody—A protein molecule produced by the immune system that is specific to a disease agent, such as CMV and the other organisms sought by the TORCH test. The antibody combines with the organism and disables it.

Perinatal—Referring to the period of time surrounding an infant's birth, from the last two months of pregnancy to the first 28 days of life. The TORCH panel tests for perinatal infections.

Small-for-gestational-age (SGA)—A term used to describe newborns who are below the 10th percentile in height or weight for their estimated gestational age. The gestational age is based upon the date of the mother's last menstrual period. SGA is one of the symptoms of TORCH syndrome.

Titer—The concentration of a substance in a given sample of blood or other tissue fluid.

Preparation

No special preparation, other than sterile technique, is required.

Risks

The only complications associated with the TORCH test are those resulting from the heelstick technique itself. These risks include scarring, infection of the bone, **cellulitis** (inflammation of cellular tissue), small lumpy **calcium** deposits, and inaccurate test results.

Results

The normal result would be normal levels of immunoglobulin M (IgM) antibody in the infant's blood. IgM is one of five types of protein molecules found in blood that function as antibodies. IgM is a specific class of antibodies that seeks out virus particles. In contrast to adults, IgM is the most common type of immunoglobulin in newborn children. It is,

therefore, the most useful indicator of the presence of a TORCH infection.

Abnormal results

The general abnormal, or positive, finding would be high levels of IgM antibody. The test can be refined further for antibodies specific to given disease agents. The TORCH screen, however, can produce both false-positive and false-negative findings. Doctors can measure IgM levels in the infant's cerebrospinal fluid, as well as in the blood, if they want to confirm the TORCH results.

Torticollis

Definition

Torticollis (cervical dystonia or spasmodic torticollis) is a type of movement disorder in which the muscles controlling the neck cause sustained twisting or frequent jerking.

Description

In torticollis, certain muscles controlling the neck undergo repetitive or sustained contraction, causing the neck to jerk or twist to the side. Cervical dystonia causes forward twisting, and is called antecollis. Backward twisting is known as retrocollis. The abnormal posture caused by torticollis is often debilitating, and is usually painful.

Torticollis most commonly begins between ages of 30 and 60, with females affected twice as often as males. According to the National Spasmodic Torticollis Association, torticollis affects 83,000 people in the United States. Dystonia tends to become more severe during the first months or years after onset, and may spread to other regions, especially the jaw, arm, or leg. Torticollis should not be confused with such other causes of abnormal neck posture as orthopedic or congenital problems.

Causes and symptoms

The nerve signals responsible for torticollis are thought to originate in the basal ganglia, a group of brain structures involved in movement control. The exact defect is unknown. Some cases of dystonia are due to the inheritance of a defective gene, whose function was unknown as of 2014. Other cases are correlated with neck or head **trauma**, such as from an automobile accident. Use of certain **antipsychotic drugs**, or neuroleptics, can induce dystonia.

There are three types of torticollis:

- tonic, in which the abnormal posture is sustained
- clonic, marked by jerky head movements
- mixed, a combination of tonic and clonic movements

Symptoms usually begin gradually, and may be intermittent at first, worsening in times of **stress**. Symptoms usually progress over two to five years, and then remain steady. Symptoms may be relieved somewhat when lying down. Many people with torticollis can temporarily correct their head position by sensory tricks, as touching the chin or cheek on the side opposite the turning. The reason for the effectiveness of this "geste antagoniste," as it is called, is unknown.

Pain in the neck, back, or shoulder affects more than two-thirds of all people with torticollis. Pain may spread to the arm or hand.

Diagnosis

Diagnosis of torticollis is aided by an electrical study (**electromyography**) that can detect overactive muscles. Imaging studies, including x rays, may be done to rule out other causes of abnormal posture. A detailed medical history is needed to determine possible causes, including trauma.

Treatment

A variety of oral drugs are available to relax muscles, including baclofen. For a subgroup of patients, L-dopa provides effective relief. Denervation of the involved neck muscles may be performed with injection of alcohol or phenol into the nerve.

Injection of botulinum toxin (BTX) is considered by many to be the treatment of choice. By preventing release of chemical messages from the nerve endings that stimulate the involved muscles, BTX partially paralyzes the muscles, allowing more normal posture and range of motion. BTX treatment lasts several months, and may be repeated.

Physical therapy can help relieve secondary consequences of torticollis. Regular muscle stretching prevents contracture, or permanent muscle shortening.

WWW.BOOKBAZ.IR

Pain and spasm may be temporarily lessened with application of heat or ice. Stress management techniques may help prevent worsening. An occupational therapist can suggest home or work modifications to reduce **fatigue** and improve function. Braces constructed to replace the patient's own sensory tricks may help reduce abnormal posture.

Deep Brain Stimulation (DBS) delivers electrical pulses to specific areas of the brain that control movement. The treatment uses the Activa® Therapy, which involves electrodes placed into the brain. Persons using this form of treatment are monitored frequently by a neurologist trained in DBS.

Selective Denervation Surgery is a treatment that may be considered if other, less invasive, treatments are not successful in helping to reduce symptoms. This procedure removes nerves that activate the muscles involved in torticollis. While this procedure has a high success rate, it is not reversible, is costly and carries risk. Patients must meet certain criteria in order to qualify for this surgery. Following surgery, there is a higher chance for success if physical therapy is utilized.

Alternatives

Biofeedback may be effective for some patients. Regular **massage therapy** can reduce additional pain in compensating areas of the body. Two energy-based therapies, **acupuncture** and **homeopathic medicine**, can work to rebalance the whole person, helping to correct the torticollis. Antispasmodic herbs may help to relax the muscles. In addition, herbs that can help balance the stimulus from the nervous system are often recommended.

Prognosis

Spontaneous remission is seen in up to 20% of patients, most often those patients with older onset and milder symptoms. Dystonia may spread to affect other regions of the body.

Prevention

There is no way known to prevent torticollis.

Total parenteral nutrition

Definition

Total parenteral nutrition (TPN) is a way of supplying all the nutritional needs of the body by bypassing the digestive system and by administering nutrient solution directly into a vein. Other terms used synonymously with TPN include parenteral nutrition and hyperalimentation.

Purpose

TPN is used when individuals cannot or should not get their nutrition through eating. TPN is used when the intestines are obstructed, when the small intestine is not absorbing nutrients properly, or when a gastrointestinal fistula (abnormal connection) is present. It is also used when the bowels need to rest and should not have any food passing through them. Bowel rest may be necessary in Crohn's disease, pancreatitis, ulcerative colitis, and with prolonged bouts of diarrhea in young children. TPN is also used for individuals with severe burns, multiple fractures, and in malnourished individuals to prepare them for major surgery, chemotherapy, or radiation treatment. Individuals with AIDS or widespread infection (sepsis) and other medical conditions may also benefit from the administration of TPN.

Description

TPN is normally given through a large central vein. A catheter is inserted into the vein in the chest

Food-mood connection

area under local anesthesia and sterile conditions. Placement may be done in an operating room to decrease the chance of infection. Several different types of catheters are used based on the reason TPN is needed and the expected length of treatment. Catheters are made of silicone or similar materials. Once the catheter is in place, a chest x ray is done to make sure the placement is correct.

Normally TPN is administered in a hospital, but under certain conditions and with proper patient and caregiver education, it may also be used at home for long–term therapy. TPN solution is mixed daily under sterile conditions. Maintaining sterility is essential for preventing infection. For this reason, the outside tubing leading from the bag of solution to the catheter is changed daily, and special dressings covering the catheter are changed daily as well.

The contents of the TPN solution are determined based on the age, weight, height, and medical condition of the individual. All solutions contain sugar (dextrose) for energy and protein (amino acids). Fats (lipids) may also be added to the solution. Electrolytes such as potassium, sodium, calcium, magnesium, chloride, and phosphate are also included, as these are essential to the normal functioning of the body. Trace elements such as zinc, copper, manganese and chromium are also needed. Vitamins can be included in the TPN solution, and insulin, a hormone that helps the body use sugar, may need to be added. Adults need approximately 2L of TPN solution daily, although this amount varies with age, size, and health of the individual. Special solutions have been developed for individuals with reduced liver and kidney function. The solution is infused slowly at first to prevent fluid imbalances, then the rate is gradually increased. The infusion process takes several hours.

Successful TPN requires frequent, often daily, monitoring of the individual's weight, glucose (blood sugar) level, blood count, blood gases, fluid balance, urine output, waste products in the blood (plasma urea) and electrolytes. Liver and kidney function tests may also be performed. Contents of the solution are individualized based on the results of these tests.

Precautions

Individuals need to tell their doctor if they have any allergies, what medications they are taking, if they are diabetic, have had liver, kidney, heart, lung, or hormonal disorders, and if they are pregnant. All these factors can affect the type and amount of TPN required.

KEY TERMS

Catheter—A hollow tube that is inserted into veins or other passages in the body to insert or remove fluid.

Electrolyte—An ion such as potassium, sodium, or chloride dissolved in fluid that helps to regulate metabolic activities of cells.

Fistula—An abnormal passage that connects one organ to another or that connects the organ to the outside of the body.

Preparation

Preparation to insert the catheter involves creating a sterile environment. Other special preparations are not normally necessary.

Aftercare

During the time the catheter is in place, patients and caregivers must be alert to any signs of infection such as redness, swelling, fever, drainage, or pain.

Risks

TPN requires close monitoring. Two types of complications can develop. Infection, air in the lung cavity (pneumothorax), and blood clot formation (thrombosis) all can develop as a result of inserting the catheter into a vein. Metabolic and fluid imbalances can occur if the contents of the nutritional fluid are not properly balanced and monitored. The most common metabolic imbalance is hypoglycemia, or low blood sugar, caused by abruptly discontinuing a solution high in sugar.

Most of the time, TPN is administered through an infusion pump so that delivery of the fluids can be precisely monitored and calculated.

Results

Ideally TPN will provide all nutrients in the correct quantity to allow the body to function normally.

Tourette syndrome

Definition

Tourette syndrome (TS) is an inherited disorder of the nervous system that typically appears in childhood. The main features of TS are repeated movements and vocalizations called tics. TS can also be associated with behavioral and developmental problems.

Demographics

Tourette syndrome is a relatively common disorder found in all populations and all ethnic groups. TS is three to four times more common in males than females. The exact incidence of Tourette syndrome is unknown but it is estimated to affect 1–10 in 1,000 children. According to the National Institute for Neurological Disorders and **Stroke** (NINDS), an estimated 200,000 Americans have the most severe form of TS, and as many as one in 100 have milder symptoms such as chronic motor or vocal tics. Early TS symptoms are almost always noticed first in childhood, with the average onset between the ages of 7 and 10 years.

Description

Tourette syndrome is a variable disorder with onset in childhood. Though symptoms can appear anywhere between the ages of 2 and 18, typical onset is around age 6 or 7. Tics, which may be motor or vocal, tend to wax and wane (increase and decrease) in severity over time. The first references in the literature to what might today be classified as TS largely describe individuals who were wrongly believed to be possessed by the devil. In 1885 Gilles de la Tourette, a French neurologist, provided the first formal description of this syndrome, which he described as an inherited neurological condition characterized by motor and vocal tics.

Although vocal and motor tics are the hallmark of Tourette syndrome, other symptoms such as the expression of socially inappropriate comments or behaviors, obsessive compulsive disorder, attention deficit disorder, self injuring behavior, depression, and **anxiety** also appear to be associated with Tourette syndrome. Symptoms usually intensify during teenage years and diminish in late adolescence or early adulthood. Patients may also develop co–occurring behavioral disorders, namely obsessive–compulsive disorder (OCD), **attention deficit hyperactivity disorder (ADHD)** or attention deficit disorder (ADD), poor impulse control, and/or **sleep disorders**. Though some children have learning disabilities, intelligence is not impaired. TS is not degenerative and life span is normal.

Risk factors

As of 2014, TS risk factors are unknown, and researchers are studying risk factors before and after birth that may contribute to this complex disorder. Some of the suggested factors include severe psychological **trauma**, recurrent daily stresses, extreme emotional excitement, PANDAS (pediatric autoimmune neuropsychiatric disorder with streptococcal infection), and drug abuse.

Causes and symptoms

A variety of genetic and environmental factors likely play a role in causing TS. Studies suggest that the tics in Tourette syndrome are caused by an increased amount of a neurotransmitter called dopamine. A neurotransmitter is a chemical found in the brain that helps to transmit information from one brain cell to another. Other studies suggest that the defect in Tourette syndrome involves another neurotransmitter called serotonin or involves other chemicals required for normal functioning of the brain.

Genetic factors are believed to play a major role in the development of TS. Several chromosomal regions have been identified as possible locations of genes that confer susceptibility to TS. Some family studies have indicated that TS may be inherited in an autosomal dominant manner, but other studies have shown that this is not the case. Mutations involving the SLITRK1 gene have been identified in a small number of TS patients. This gene provides instructions for making a brain protein called SLITRK1. This protein probably plays a role in the development of nerve cells, including the growth of axons and dendrites that allow each nerve cell to communicate with nearby cells. It is unclear how mutations in the SLITRK1 gene can lead to this disorder. The inheritance pattern of Tourette syndrome remains unknown. Although the features of TS can cluster in families, many genetic and environmental factors are likely to be involved. Some researchers believe that Tourette syndrome has

different causes in different individuals or is caused by changes in more than one gene. Further research is needed to establish the cause of Tourette syndrome.

Motor and vocal tics

The principal symptoms of Tourette syndrome include simple and complex motor and vocal tics. Simple motor tics are characterized by brief muscle contractions of one or more limited muscle groups. An eye twitch is an example of a simple motor tic. Complex motor tics tend to appear more complicated and purposeful than simple tics and involve coordinated contractions of several muscle groups. Some examples of complex motor tics include the act of hitting oneself and jumping. Copropraxia, the involuntary display of unacceptable/obscene gestures, and echopraxia, the imitation of the movement of another individual, are other examples of complex motor tics.

Vocal tics are actually manifestations of motor tics that involve the muscles required for vocalization. Simple vocal tics include **stuttering**, stammering, abnormal emphasis of part of a word or phrase, and inarticulate noises such as throat clearing, grunts, and high–pitched sounds. Complex vocal tics typically involve the involuntary expression of words. Perhaps the most striking example of this is coprolalia, the involuntary expression of obscene words or phrases, which occurs in fewer than one–third of people with Tourette syndrome. The involuntary echoing of the last word, phrase, sentence or sound vocalized by oneself (phalilalia) or of another person or sound in the environment (echolalia) are also classified as complex tics.

The type, frequency, and severity of tics exhibited varies tremendously between individuals with Tourette syndrome. Tourette syndrome has a variable age of onset and tics can start anytime between infancy and age 18. Initial symptoms usually occur before the early teens and the mean age of onset for both males and females is approximately seven years of age. Most individuals with symptoms initially experience simple muscle tics involving the eyes and the head. These symptoms can progress to tics involving the upper torso, neck, arms, hands, and occasionally the legs and feet. Complex motor tics are usually the latest onset muscle tics. Vocal tics usually have a later onset then motor tics. In some rare cases, people with Tourette syndrome suddenly present with multiple, severe, or bizarre symptoms.

Not only is there extreme variability in clinical symptoms between individuals with Tourette syndrome, but individuals commonly experience a variability in type, frequency, and severity of symptoms within the course of their lifetime. Adolescents with Tourette syndrome often experience unpredictable and variable symptoms, which may be related to fluctuating hormone levels and decreased compliance in taking medications. Adults often experience a decrease in symptoms or a complete end to symptoms.

A number of factors appear to affect the severity and frequency of tics. **Stress** appears to increase the frequency and severity of tics while concentration on another part of the body that is not taking part in a tic can result in the temporary alleviation of symptoms. Relaxation, following attempts to suppress the occurrence of tics, may result in an increased frequency of tics. An increased frequency and severity of tics can also result from exposure to drugs such as **steroids**, cocaine, amphetamines, and **caffeine**. Hormonal changes such as those that occur prior to the menstrual cycle can also increase the severity of symptoms.

Other associated symptoms

People with Tourette syndrome are more likely to exhibit non–obscene, socially inappropriate behaviors such as expressing insulting or socially unacceptable comments or socially unacceptable actions. It is not known whether these symptoms stem from a more general dysfunction of impulse control that might be part of Tourette syndrome.

Tourette syndrome appears to also be associated with attention deficit disorder (ADD). ADD is a disorder characterized by a short attention span and impulsivity and in some cases hyperactivity. Researchers have found that 21–90% of individuals with Tourette syndrome also exhibit symptoms of ADD, whereas 2–15% of the general population exhibit symptoms of ADD.

People with Tourette syndrome are also at higher risk for having symptoms of obsessive–compulsive disorder (OCD). OCD is a disorder characterized by persistent, intrusive, and senseless thoughts (obsessions) or compulsions to perform repetitive behaviors that interfere with normal functioning. A person with OCD, for example, may be obsessed with germs and may counteract this obsession with continual hand washing. Symptoms of OCD are present in 2–3% of the general population, whereas 28–50% of people with Tourette syndrome have symptoms of OCD.

Self–injurious behavior (SIB) is also seen more frequently in those with Tourette syndrome. Approximately 34–53% of individuals with Tourette syndrome exhibit some form of self–injuring behavior. The SIB is often related to OCD but can also occur

WWW.BOOKBAZ.IR

in those with Tourette syndrome who do not have OCD.

Symptoms of anxiety and depression are also found more commonly in people with Tourette syndrome. It is not clear whether these symptoms are symptoms of Tourette syndrome or occur as a result of having to deal with the symptoms of moderate to severe Tourette syndrome.

People with Tourette syndrome may also be at increased risk for having learning disabilities and **personality disorders** and may be more predisposed to behaviors such as aggression, antisocial behaviors, severe temper outbursts, and inappropriate sexual behavior. Further controlled studies need to be performed to ascertain whether these behaviors are symptoms of Tourette syndrome.

Diagnosis

Examination

The TS diagnosis is made through observation and interview of the patient and discussions with other family members. The diagnosis of Tourette syndrome is complicated by a variety of factors. The extreme range of symptoms of this disorder makes it difficult to differentiate Tourette syndrome from other disorders with similar symptoms. Diagnosis is further complicated by the fact that some tics appear to be within the range of normal behavior. For example, an individual who only exhibits tics such as throat clearing and sniffing may be misdiagnosed with a medical problem such as **allergies**. In addition, bizarre and complex tics such as coprolalia may be mistaken for psychotic or "bad" behavior. Diagnosis is also confounded by individuals who attempt to control tics in public and in front of healthcare professionals and deny the existence of symptoms. Although there is disagreement over what criteria should be used to diagnosis Tourette syndrome, one aid in the diagnosis is the *Diagnostical and Statistical Manual of Mental Disorders* (*DSM–IV*). The *DSM–IV* outlines suggested diagnostic criteria for a variety of conditions including Tourette syndrome such as:

- Presence of both motor and vocal tics at some time during the course of the illness.
- The occurrence of multiple tics nearly every day through a period of more than one year, without a remission of tics for a period of greater than three consecutive months.
- The symptoms cause distress or impairment in functioning.
- Age of onset of prior to 18 years of age.
- The symptoms are not due to medications or drugs and are not related to another medical condition.

Some physicians critique the *DSM–IV* criteria, citing that they do not include the full range of behaviors and symptoms seen in Tourette syndrome. Others criticize the criteria since they limit the diagnosis to those who experience a significant impairment, which may not be true for individuals with milder symptoms. For this reason many physicians use their clinical judgment as well as the *DSM–IV* criteria as a guide to diagnosing Tourette syndrome.

KEY TERMS

Attention deficit disorder (ADD)—Disorder characterized by a short attention span, impulsivity, and in some cases hyperactivity.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Axon—The long extension of a nerve fiber that generally conducts impulses away from the body of the nerve cell.

Coprolalia—The involuntary expression of obscene words or phrases.

Copropraxia—The involuntary display of unacceptable/obscene gestures.

Decreased penetrance—Individuals who inherit a changed disease gene but do not develop symptoms.

Dendrites—Fibers of a brain cell that receive signals from other brain cells.

Dysphoria—Feelings of anxiety, restlessness, and dissatisfaction.

Echolalia—Involuntary echoing of the last word, phrase, or sentence spoken by someone else or sound in the environment.

Echopraxia—The imitation of the movement of another individual.

Neurotransmitter—Chemical in the brain that transmits information from one nerve cell to another.

Obsessive compulsive disorder (OCD)—Disorder characterized by persistent, intrusive, and senseless thoughts (obsessions) or compulsions to perform repetitive behaviors that interfere with normal functioning.

Phalilalia—Involuntary echoing of the last word, phrase, sentence, or sound vocalized by oneself.

Tic—Brief and intermittent involuntary movement or sound.

Tests

Patients may undergo blood tests, imaging studies such as **magnetic resonance imaging** (MRI), or an electroencephalogram (EEG) scan in order to rule out other possible explanations for the symptoms.

Treatment

There is no cure for Tourette syndrome, and treatment involves the control of symptoms through educational and psychological interventions and/or medications. The treatment and management of Tourette syndrome varies from patient to patient and is typically focused on the alleviation of the symptoms that are most bothersome to the patient or that cause the most interference with daily functioning.

Traditional

Psychological treatments such as counseling are not generally useful for the treatment of tics but can be beneficial in the treatment of associated symptoms such as OCD and ADD. Counseling may also help individuals to cope better with the symptoms of this disorder and to have more positive social interactions. Psychological interventions may also help people cope better with stressors that can normally be triggers for tics and negative behaviors. Relaxation therapies may, however, increase the occurrence of tics. Treatment is crucial in helping the affected child avoid depression, social **isolation**, and strained family relationships. The education of family members, teachers, and peers about Tourette syndrome can be helpful and may help to foster acceptance and prevent social isolation.

Drugs

Many people with mild symptoms of Tourette syndrome never require medications. Those with severe symptoms may require medications for all or part of their lifetime. No single or combination (more than one) drug therapy offers complete cessation of symptoms without adverse effects. The most effective treatment of tics associated with Tourette syndrome involves the use of drugs such as Haloperidol, Pimozide, Sulpiride, and Tiapride, which decrease the amount of dopamine in the body. Unfortunately, the incidence of side effects, even at low dosages, is quite high. The short–term side effects can include **sedation**, dysphoria, weight gain, movement abnormalities, depression, and poor school performance. Long–term side effects can include **phobias**, memory difficulties, and personality changes. These drugs are better candidates for short–term rather than long–term therapy.

Tourette syndrome can also be treated with other drugs such as clonidine, clonazepam, and risperidone, but the efficacy of these treatments is unknown. In many cases, treatment of associated conditions such as ADD and OCD is often more of a concern than the tics themselves. Clonidine used in conjunction with stimulants such as Ritalin may be useful for treating people with Tourette syndrome who also have symptoms of ADD. Stimulants should be used with caution in individuals with Tourette syndrome since they can sometimes increase the frequency and severity of tics. OCD symptoms in those with Tourette syndrome are often treated with drugs such as Prozac, Luvox, Paxil, and Zoloft.

In many cases the treatment of Tourette syndrome with medications can be discontinued after adolescence. Trials should be performed through the gradual tapering off of medications and should always be done under a doctor's supervision.

Alternatives

Clinical trials for the treatment of Tourette syndrome are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2009, NIH reported 22 ongoing or recently completed studies. Some examples include the following:

- A study to investigate how the sensitivity to touch and smell in patients with Tourette syndrome may differ from that of people without TS. (NCT00368433)
- The evaluation of whether deep brain stimulation is effective at reducing tic frequency and severity in adults with Tourette syndrome. (NCT00311909)
- A study using magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS) of the brain to try to gain a better understanding of the disease process in Tourette's syndrome. (NCT00030953)

Clinical trial information is constantly updated by NIH and the most recent information on Tourette syndrome trials can be found at: http://clinicaltrials.gov.

Prognosis

The prognosis for Tourette syndrome in individuals without associated psychological conditions is often quite good, and only approximately 10% of Tourette syndrome individuals experience severe tic symptoms. Approximately 30% of people with Tourette syndrome will experience a decrease in the frequency and severity of tics and another 30–40% will experience a complete end of symptoms by late adolescence. The other 30–40% will continue to exhibit moderate to severe symptoms in adulthood. There does not appear to be a definite correlation between

WWW.BOOKBAZ.IR

the type, frequency, and severity of symptoms and the eventual prognosis. Patients with severe tics may experience social difficulties and may isolate themselves from others in fear of shocking and embarrassing them. People with Tourette syndrome who have other symptoms such as OCD, ADD, and self–injurious behavior usually have a poorer prognosis.

Prevention

There is no known way to prevent Tourette syndrome.

Toxic encephalopathy *see* **Delirium**

Toxic epidermal necrolysis

Definition

Toxic epidermal necrolysis (TEN) is a rare condition that causes large portions of the epidermis, the skin's outermost layer, to detach from the layers of skin below. A reaction to a medication is the primary cause.

Description

TEN begins with **fever**, **cough**, and other nonspecific symptoms, and is soon followed by purplish, bloody-looking lesions on the skin and mucous membranes. These early lesions, typically found on the head, neck, and upper chest, soon merge and blister. Sheets of epidermis then begin to detach from the skin layers below. In time, the entire surface of the skin may be involved, with detachment of 100% of the epidermis.

Causes and symptoms

The main cause of TEN is a severe drug reaction. Some investigators believe there may be additional infectious causes. A severe reaction in transplant patients, called **graft-vs.-host disease**, can also produce TEN.

One study reported more than 100 different drugs as causes of TEN. The drugs most commonly implicated include antibacterial **sulfonamides** such as sulfadiazine, **antibiotics** such as aminopenicillins and **cephalosporins**, and anticonvulsants like phenytoin. TEN is extremely rare. Researchers estimate that there are 0.2 cases per million users of aminopenicillins and 4.5 cases per million users of sulfonamides.

Exactly what leads to detachment of the epidermis remains unclear. People with TEN seem to have difficulty metabolizing the offending drug. Some researchers suggest that certain substances that should be cleared from the body instead get deposited on the outer shell of the epidermis, causing an immune response that leads the body to "reject" the skin.

Diagnosis

Diagnosis is made primarily on the appearance and spread of the **skin lesions**, and on a history that includes introduction of a new medication within the previous one to three weeks. A biopsy of the early lesions will confirm the diagnosis. Physicians will consider other potential diseases that cause similar symptoms before reaching a diagnosis of TEN. One is **erythema multiforme**, a recurrent skin disorder that produces lesions similar in appearance to TEN. However, this disorder is not caused by a drug reaction and does not lead to sheet-like shedding of the skin. Another disease, Stevens-Johnson syndrome, is a drug-induced skin disease that some experts believe is really a milder form of TEN. **Staphylococcal scalded skin syndrome** (SSSS) also looks like TEN, but it is caused by a staphylococcal infection. Unlike TEN, which occurs rarely in children, SSSS primarily affects infants, young children, and adults with weakened immune systems.

Treatment

There is no specific treatment for TEN. Patients are typically treated in an intensive care unit or in a burn unit and receive treatment similar to that given to patients with major **burns**. With the loss of skin, severe **dehydration** is a major risk, so healthcare workers will attempt to replace fluids intravenously. Nutritional supplementation from a tube routed through the nose to the stomach may also be contemplated to promote the healing of the skin. Infection is a major risk, so some physicians "paint" the open lesions with topical **antiseptics**. Others use skin grafts taken from cadavers or cultured skin substitutes to cover large open areas until healing can occur. Some investigators believe system **corticosteroids** are useful in the treatment of TEN. But since these medications have also been implicated as a cause in some cases of TEN and are known to supress the immune system, their use should be considered carefully.

KEY TERMS

Epidermis—The outermost layer of the skin.

Erythema multiforme—A recurrent skin disorder that produces lesions similar in appearance to TEN, but is not caused by a drug reaction and does not lead to sheet-like shedding of the skin.

Staphylococcal scalded skin syndrome—A disease caused by *Staphylococcus aureus,* in which large sheets of skin may peel away from the body. It most often affects infants, young children, and people with weakened immune systems.

Stevens-Johnson syndrome—A drug-induced skin disease that some experts believe is really a milder form of TEN.

Prognosis

About 25-30% of patients with TEN die. Elderly patients, those with extensive skin lesions, and those with **AIDS** have the worst prognosis. Widespread systemic infection (**sepsis**) is the primary cause of death. Survivors, however, will be completely healed in three to four weeks.

Prevention

There is no prevention for TEN. No reliable test can indicate that a specific drug may cause TEN in a specific patient. Some researchers believe skin tests of potentially offending drugs may prove useful in the future.

Toxic shock syndrome

Definition

Toxic shock syndrome (TSS) is an uncommon, but potentially fatal, illness that occurs when poisonous substances (toxins) produced by certain bacteria enter the bloodstream. TSS is a medical emergency and requires immediate medical attention.

WWW.BOOKBAZ.IR

Demographics

Although TSS is, in the public mind, most strongly associated with healthy women who used super-absorbent tampons during the 1980s and developed the syndrome, children and men also can develop TSS. At its height between 1980 and 1984, TSS affected 15,000 people in the United States annually. Once the cause of the syndrome was understood and the offending tampons were removed from the market, the rate dropped sharply. Although in 2010, TSS was uncommon (only 1–3 cases per 100,000 population), the rate is increasing, most likely due to an increase in strains of antibiotic-resistant bacteria that can cause the syndrome.

Description

TSS first came to the attention of the public in the late 1970s. Shortly after the introduction of super-absorbent tampons, young women across the United States experienced an epidemic of serious but unexplained symptoms. Thousands went to emergency rooms with high **fever**, **vomiting**, peeling skin, low blood pressure, **diarrhea**, and a rash resembling **sunburn**. The only thing they had in common was that they all were menstruating at the time they felt sick, and all were using tampons, especially super-absorbent products.

Despite the association of TSS and menstruating women, the disease can affect anyone of either sex or any age or race. The infection may occur in children, men, and non-menstruating women who are weakened from surgery, injury, or disease, and who cannot fight off a staphylococcal infection. New mothers also are at higher risk for TSS.

Two kinds of toxic shock syndrome are recognized. Traditional toxic shock or TSS is caused by staphylococcus bacteria. Another form of toxic shock caused by streptococcal bacteria was recognized in 1987; it is referred to as Streptococcal toxic shock syndrome or (STSS). STSS is related to the strain of streptococcus nicknamed the "flesh-eating bacterium." It affects only one or two out of every 100,000 Americans. STSS almost never follows a simple **strep throat** infection. Sometimes STSS is referred to as toxic shock-like syndrome or TSLS.

Risk factors

People who are most likely to develop TSS are between the ages of 15 and 35. STSS is most likely to affect people between the ages of 20 and 50. Other risk factors include just having given birth, extended use of packing material to stop blood flow (e.g. tampons, packing to stop a nose bleed), the use of barrier contraceptives (e.g., diaphragm, vaginal sponge, especially if left in a long time) recent surgery, a recent staphylococcal or streptococcal infection and recent varicella (**chickenpox**) infection.

Causes and symptoms

TSS is caused by staphylococcal bacteria, most often a specific strain of *Staphylococcus aureus* found in the nose, mouth, and occasionally the vagina. The bacteria produce a characteristic toxin. In large enough quantities, the toxin enters the bloodstream and causes a potentially fatal infection.

These types of bacteria normally are present either on hands or in the vagina, and it takes an amount of bacteria only the size of a grain of sand to start an infection. Of the 15% of women who carry *S. aureus*, only about 5% have the strain that produces the TSS toxin. STSS is caused by streptococcal bacteria, most often a specific strain of *Streptococcus pyogenes*.

TSS begins with 2–3 day period of mild symptoms, then symptoms escalate suddenly, with a high fever of 102°F (38.9°C) or above, vomiting and watery diarrhea, **headache**, and sunburn-like rash, together with a **sore throat** and body aches. Blood pressure may plummet a day or two after the first symptoms appear. When the blood pressure drops, an individual may become disoriented or go into shock. The kidneys may fail. After these developments, the skin on the hands and feet may peel. Symptoms of STSS are usually more serious and severe than those of TSS, although both variations of the syndrome can be fatal.

Diagnosis

No specific tests will diagnose TSS or STSS. A **complete blood count** (CBC) and blood cultures, blood electrolyte measurements, **urinalysis**, renal (Kidney) function and **liver function tests**, imaging studies, and an electrocardiogram (ECG) may be done to rule out other diseases and to indicate the direction of treatment.

Treatment

TSS and STSS are medical emergencies. Individuals who suspect that they have this syndrome should go to the emergency department immediately.

Individuals will be hospitalized usually in an intensive care unit (ICU), possibly for an extended period. All foreign packing material should be removed from the body as soon as possible. The first step in treatment is to stabilize the individual, which

KEY TERMS

Electrocardiogram (ECG, EKG)—A test that records the electrical activity of the heart using small electrode patches attached to the skin on the chest.

Electrolyte—Salts and minerals that ionize in body fluids. The major human electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), phosphate (HPO_4^{2-}), bicarbonate (HCO_3-), and sulfate (SO_4^{2-}). Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Shock—A condition in which the amount of blood circulating in the body is inadequate to meet the body's needs. Shock can be caused by certain diseases, serious injury, or blood loss.

Staphylococcus—A genus of bacteria that is commonly found on human skin and mucous membranes.

Streptococcus—A genus of sphere-shaped bacteria that can cause a wide variety of infections.

Toxin—A poisonous protein that is produced by some bacteria. A toxin is less complex than a poison.

may involve giving oxygen, medications to increase blood pressure, or **kidney dialysis** if the kidney is failing and ventilator support if breathing is impaired. The second part of treatment involves the administration of intravenous (IV) **antibiotics** and sometimes surgery to eliminate the infection. The increasing prevalence of strains of antibiotic-resistant bacteria may make it necessary to use multiple antibiotics to control the infection. The final step of treatment involves, where possible, reversing any damage caused by the bacterial toxins. This may involve surgery to remove dead or damaged tissue.

Prognosis

Untreated TSS/STSS can be fatal. Even with treatment, about 5% of individuals with TSS die and up to 70% of individuals with STSS die. Individuals with diabetes, compromised immune systems, the very young, and the elderly are most likely to die. Rapid treatment increases the chance of survival. Survivors may experience long-term kidney damage, memory and concentration problems, lung damage, and nervous system abnormalities. The syndrome recurs within two months in 30–50% of individuals, although recurrence is generally less severe than the initial infection.

Prevention

Women who wear tampons should wash their hands before inserting the tampon and change tampons often (every 4–6 hours). **Wounds** should be kept clean and dressings changed regularly. Some of the more serious complications can be reduced or prevented by seeking emergency medical care as soon as TSS/STSS is suspected. This is not a condition that can be successfully treated with **home care** or alternative therapies.

Toxicology screen

Definition

A toxicology screen, also known as a tox screen or drug test, is a test or set of tests done on body fluids, tissues, or organs to determine the type and amount(s) of prescription drugs, alcohol, drugs of abuse, heavy metals, or other toxic substances in the body. The examiner may test for one substance at a time or up to 30 different drugs at once.

Screening for the type of substance(s) involved is known as qualitative testing; examination of the amount(s) involved is called quantitative testing. Qualitative testing is the most common form of analysis in toxicology screening; quantitative testing is performed most often as a follow-up procedure to confirm the results of qualitative testing.

WWW.BOOKBAZ.IR

Purpose

The drugs most commonly tested during toxicology screens include:

- ethanol (beverage alcohol)
- barbiturates, methaqualone, and other sleep medications
- benzodiazepines and other tranquilizers
- antidepressants
- date rape drugs
- cocaine
- THC (the active compound in marijuana)
- narcotics (opium and opioid painkillers, including heroin, propoxyphene, morphine, oxycodone, and hydrocodone)
- phencyclidine (PCP or angel dust)
- antipsychotic drugs
- acetaminophen and other non-narcotic pain relievers
- amphetamines
- steroids

There are many different reasons for tox screens:

- Toxicology screens are frequently performed in the emergency department of a hospital to evaluate patients with symptoms of drug or alcohol intoxication or overdose; to distinguish between substance abuse or intoxication and psychiatric or medical conditions such as psychosis, dementia, or delirium; and to determine the appropriate course of treatment.
- Toxicology screens are often used to screen job applicants prior to employment for abuse of alcohol or illegal drugs, or for random testing of current employees. Workplace drug testing is particularly common in industries and occupations in which the safety of other workers or the general public may be affected by drug abuse, such as transportation, construction, mining, demolition, healthcare, and retail.
- Tox screens are performed in sports medicine to test student and professional athletes for the use of performance-enhancing drugs (doping), including anabolic steroids, human growth hormone, erythropoietin, and androstenedione. The screens are done not only to guarantee the fairness of athletic competition, but also to protect participants against the long-term side effects of these drugs, which include infertility, delayed growth (in adolescents), liver disorders, high blood pressure, psychiatric disorders, and heart problems.
- Drug testing is sometimes performed to monitor a patient's compliance with prescribed medications, particularly barbiturates, amphetamines, and opiates and other drugs given for pain management. Tox screens may also be done as part of addiction treatment. In some cases, a drug screen may be done to find out whether a patient's body is absorbing and processing prescription medications properly.
- Newborn infants whose mothers are known or suspected to have abused alcohol or illicit drugs during pregnancy can be tested shortly after birth for the presence of these substances or their metabolites (breakdown products). In addition to blood or urine samples, the infant's meconium (the first stool produced after delivery) can be tested for drugs of abuse. Meconium testing is presently considered the most accurate method of screening for maternal drug abuse during pregnancy.
- Drivers suspected of operating a motor vehicle under the influence of alcohol, marijuana, or other drugs may be asked to take a breathalyzer test or provide a blood sample at the police station or a medical facility.
- Women who have been sexually assaulted may be given a urine test at the hospital to assess the presence of drugs like flunitrazepam (Rohypnol), ketamine, or gamma-hydroxybutyric acid (GHB), often referred to as date rape drugs.
- Toxicology screening is used during the process of drug development to study the ways that drugs are metabolized in the body, their interactions with other drugs, their side effects, their potential for dependence or addiction, and the difference between a therapeutic dose and a toxic or lethal one.
- Toxicology screening may used on people affected by the venom from an animal bite or sting; this type of screen falls within the field of veterinary toxicology.
- Toxicology screens may also be run postmortem if drugs or other substances are suspected in the cause of death. This type of screening is known as forensic toxicology.

Description

A toxicology screen may involve a number of different health professionals, depending on the location of the test, its purpose, the patient's condition, and the legal implications of the test, if any:

- Nurses may administer or supervise the collection of urine, hair, sweat, or oral fluid samples; they are also qualified to perform venipuncture to collect a blood sample.
- A phlebotomist is a healthcare worker with specialized training in venipuncture (the collection of blood from a vein for purposes of testing or research). Phlebotomists may work in hospitals, outpatient clinics, or diagnostic testing facilities.

- Emergency physicians have specialized training in the assessment, diagnosis, and treatment of patients brought to a hospital emergency department, including those with suspected drug or alcohol intoxication or overdose.
- A medical toxicologist is a physician with advanced training in diagnosing and treating adverse drug reactions, poisoning, and occupational exposure to toxins, as well as drug abuse and overdoses. Medical toxicologists may work in occupational medicine and pediatrics as well as in hospital emergency departments.
- Medical review officers are licensed physicians who are in charge of reviewing the laboratory results for employer drug testing programs. They determine if there are any legitimate medical explanations for positive or abnormal tests and maintain the confidentiality of the information.
- Medical technologists and clinical chemists are professionals with specialized training in testing samples of human body fluids and tissues. Clinical chemists hold a doctoral degree in chemistry and are certified by either the American Board of Clinical Chemistry or the American Board of Forensic Toxicology.

A toxicology screen has two steps: sample collection and laboratory analysis. Clinical toxicology screens are performed on one or more samples of body fluids or tissues, including blood, urine, saliva, stomach contents, hair, and sweat.

Sample collection

BLOOD. Blood samples are usually obtained by venipuncture, typically from a vein in the forearm near the elbow. The blood is drawn by a trained professional through a needle into a vacuum tube and sent to a laboratory for analysis.

URINE. The person being tested is asked to go into a bathroom to provide what is called a clean catch urine sample; that is, a sample collected from the middle of the urinary stream. The person is instructed to wash his or her hands, clean the external genitalia with an antiseptic towelette, and begin to urinate into the toilet for a few seconds. The person should then collect about 3 oz. (89 mL) of midstream urine in the container provided by the test center, cover the container with its lid, and return it to the nurse or lab technician. Urine samples must be refrigerated if they cannot be tested within an hour of collection.

ORAL FLUID (SALIVA). There are two methods for collecting oral fluid for testing. In the first, the examiner swabs the inside of the patient's cheek with an absorbent material. In the second method, the person being tested is asked to spit into a collection tube.

STOMACH CONTENTS. Stomach contents in living patients are usually tested only in hospital emergency departments, when the person being examined for drug use or overdose has recently swallowed a toxic or potentially lethal dose of one or more drugs. The contents of the stomach are obtained by gastric lavage (stomach pumping), which involves passing a tube through the mouth or nose into the stomach, administering small quantities of warm water or saline solution, and withdrawing the contents of the stomach.

HAIR. Hair can be tested for most drugs of abuse, including alcohol, amphetamines, **narcotics**, cocaine, PCP, **marijuana**, and methamphetamines. The advantage of hair testing is that human hair retains evidence of drug use for as long as a year—much longer than body fluids. The hair can be taken from any part of the body, including the head, arms, legs, underarms, face, and pubic area. Head hair taken for sampling is cut close to the scalp; between 80 and 120 strands are needed for a toxicology screen.

SWEAT. Sweat is tested for drug use by applying a patch of absorbent material to a person's skin, leaving it in place for up to 14 days, and removing the patch for laboratory testing. The advantage of sweat testing is that it can be used when urine testing is not practical, and it is relatively resistant to tampering. The drawback of sweat testing is that it is more expensive than other screening methods and can be used for only a limited number of drugs.

Laboratory testing

Laboratory testing of body fluid or tissue samples is usually performed in two stages. The first is the screening test and uses immunoassay to detect the presence of alcohol or other drugs. If the sample tests positive for any substances, the laboratory performs a second test to confirm the results of the immunoassay. This confirmation test is most often either gas chromatography or mass spectrometry. Samples that test positive during the confirmation test may be stored in the laboratory for a period of months or even years in case of lawsuits or disputed results. Confirmation tests are particularly important in forensic toxicology because they can detect much smaller quantities of drugs in test samples than the immunoassay method.

Preparation

When possible, a patient should prepare for a toxicology screen by making a list of all prescription drugs, nonprescription medications, alcoholic beverages, illicit

WWW.BOOKBAZ.IR

drugs (if any), herbal remedies, **vitamins**, and dietary supplements taken within the last four days. This information is important to proper interpretation of the test results. Friends or family members accompanying a person affected by drugs or alcohol to a hospital emergency department should also be prepared to describe the drugs taken and the approximate quantities, if possible.

The patient should also prepare for the test by discussing any concerns with the doctor, such as the need for the test, any risks involved, the types of samples that will be taken, and the significance of the test results.

Workplace drug testing, athletic testing, and sobriety testing typically require the persons being tested to sign a consent form stating that they understand the risks of the testing and agree to have it done. Consent forms for teenage athletes usually require parents' signatures as well as the athlete's.

Persons scheduled for workplace or athletic drug testing should not drink large quantities of water before the test in the belief that the water will dilute the urine and prevent detection of drug use. Heavy water consumption will not only not affect the test results, but can also pose a danger to health.

Aftercare

Aftercare following venipuncture consists of applying pressure, a gauze pad, and adhesive tape to the puncture site. The phlebotomist or other healthcare professional will instruct the patient to hold the arm straight and upward for a few seconds, continue to apply pressure, and keep the bandage on the site for a few hours after the test.

No aftercare is needed for the other types of tests.

Risks

Risks associated with venipuncture include **pain** when the needle is inserted in the vein, a feeling of lightheadedness or **dizziness**, and swelling or a bruise (hematoma) at the site of the venipuncture. More serious risks include excessive bleeding and infection. Risks associated with gastric lavage include **nosebleed**, mechanical damage to the stomach, electrolyte imbalances, and laryngospasm. Serious complications are rare. There are no known risks associated with urine, hair, oral fluid, or sweat testing.

Persons arrested on suspicion of driving under the influence (DUI) risk more severe legal penalties for refusing a drug test than for taking the test and failing it.

Results

The results of toxicology screens can be affected by a range of factors, including:

- the person's age, sex, race or ethnicity, or overall health condition
- regular use of prescription, over-the-counter, and herbal medications or preparations
- smoking
- the length of time elapsed between drug or alcohol use and collection of the test samples
- improper collection or storage of the test samples prior to analysis
- the specific method(s) of analysis used by the laboratory that receives the test samples
- recent use of cough or cold medicines (which may produce a false positive for narcotics)
- the consumption of certain food items, such as poppy seeds or certain spices
- the presence of blood in the urine
- a scanty urine sample

Normal results include no unexpected drugs or substances in the samples and normal (therapeutic) levels of known prescription and nonprescription medications.

Abnormal results include the presence of alcohol or illicit drugs in the samples or abnormally low or high levels of prescription and nonprescription drugs in the blood, urine, or saliva. Values that are too low may indicate that the patient is not taking prescribed medications as directed or that his or her body is not metabolizing the medications normally. Values that are too high may indicate that the patient is overdosing on the medication.

In some cases, the toxicology test may fail to detect drugs taken by the patient; this is known as a false negative result. In other cases, the test may indicate the presence of a drug that the patient did not use; this is called a false positive result. Because of the possible legal and financial consequences of false positives, any test results that suggest the presence of alcohol or drug abuse should always be confirmed by a different test method.

Abnormal results may also occur if evidence suggests that the patient attempted to tamper with the sample. Suspicious urine results, for example, include urine with an abnormal temperature, gravity, or pH level, among other factors.

KEY TERMS

False negative—A test result that fails to detect a drug that the patient has used.

False positive—A test result that suggests that the patient has taken a drug that has not, in fact, been used.

Forensic—Pertaining to matters of interest to civil or criminal law.

Gas chromatography—A method for separating the various chemicals in a test sample by vaporizing a portion of a sample, mixing it with a carrier gas (usually nitrogen), and passing the mixture through a long column of adsorbent material. The different chemicals in the sample will pass through the column at different rates of speed and can then be identified.

Immunoassay—A biochemical test that measures the presence of a substance in a body fluid sample through the use of an immunoglobulin or an antibody.

Mass spectrometry—A method of analyzing a test sample by converting a portion of the sample into charged ions and measuring the electric current produced when the charged ions strike a detector. Mass spectrometry can be used to measure the quantity as well as the identity of a substance in the test sample.

Metabolite—In medicine, any substance produced during digestion or the breakdown of a drug in the body.

Pathologist—A physician with specialized training in the diagnosis of disease based on the anatomical, microscopic, chemical, or immunologic examination of tissues, organs, or entire bodies.

Phlebotomist—A person specially trained to withdraw blood from a vein for testing, research, or transfusion.

Postmortem—After death.

Screen—In medicine, any test or technique used to detect patients with a high likelihood of having a specific disease, or to detect one or more substances in body fluids or tissues.

Toxicology—The branch of science that deals with the study of drugs, poisons, and other chemicals, and their effects on human and animal bodies.

Venipuncture—The withdrawal of blood from a patient's vein for purposes of testing or research. The most common procedure used in adults involves the withdrawal of blood from the medial cubital vein near the elbow using a hypodermic needle and a vacuum tube.

Morbidity and mortality rates

There are occasional case reports of uncontrolled bleeding or nerve damage during venipuncture; one Danish study reported a rate of 443 complications per 100,000 blood withdrawals. No complications have been reported with urine, saliva, hair, or sweat tests.

Alternatives

There are no useful alternatives to toxicology screens.

Toxoplasmosis

Definition

Toxoplasmosis is an **infectious disease** caused by the one–celled protozoan parasite *Toxoplasma gondii*. Although most individuals do not experience any symptoms, the disease can be very serious, and even fatal, in individuals with weakened immune systems.

Demographics

There is no person–to–person transmission, except from an infected mother to her child in the womb. Approximately six out of 1,000 women contract toxoplasmosis during **pregnancy**. Nearly half of these maternal infections are passed on to the fetus. Known as congenital toxoplasmosis, this form of the disease is acquired at birth by approximately 3,300 infants in the United States every year. The risk of fetal infection is estimated to be between one in 1,000 to one in 10,000. In children born with toxoplasmosis, symptoms may be severe and quickly fatal, or may not appear until several months or even years after birth.

Description

Toxoplasmosis is caused by *T. gondii*. Cats, the primary carriers of the organism, become infected by eating rodents and birds infected with the organism. Once ingested, the organism reproduces in the

intestines of cats, producing millions of eggs known as oocysts, which are excreted in cat feces daily for approximately two weeks. In the United States, it is estimated that approximately 30% of cats have been infected by *T. gondii*. Oocysts are not capable of producing infection until approximately 24 hours after being excreted, but they remain infective in water or moist soil for approximately one year. When cattle, sheep, or other livestock forage through areas with contaminated cat feces, these animals become carriers of the disease. Fruits and vegetables can also become contaminated when irrigated with untreated water that has been contaminated with cat feces. In humans and other animals, the organisms produce thick–walled, dormant structures called cysts in the muscle and other tissues of the body.

Most humans contract toxoplasmosis by eating cyst–contaminated raw or undercooked meat, vegetables, or milk products. Humans can also become infected when they come into contact with *T. gondii* eggs while cleaning a cat's litter box, gardening, or playing in a sandbox, for instance. Once infected, an individual is immune to reinfection. The incubation period or period between infection and the start of the disease ranges from several days to months.

Anyone can be infected by *T. gondii*, but usually only those individuals with weakened immune systems (immunocompromised) develop symptoms of the disease. For them, toxoplasmosis can be severe, debilitating, and fatal. Immunocompromised individuals at risk include those with **AIDS**, cancer, or other chronic illnesses.

KEY TERMS

Cyst—The thick–walled dormant form of many organisms.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

Oocyst—The egg form of the toxoplasmosis organism.

Protozoan—A single–celled, usually microscopic, organism.

Causes and symptoms

Healthy individuals do not usually display symptoms. When symptoms do occur, they are usually mild, resembling **infectious mononucleosis**, and include the following:

- enlarged lymph nodes
- muscle pains
- intermittent fever
- general sick feeling

The distinction is made between acquired toxoplasmosis, in which an individual becomes infected, and neonatal congenital toxoplasmosis, in which a fetus is born with the infection because the mother became infected during pregnancy. If a fetus becomes infected early in pregnancy, the disease can cause the fetus to spontaneously abort or be stillborn. If full–term, the infant may die in infancy or have central nervous system lesions. If the mother becomes infected in the last three months of pregnancy the prognosis is good, and the baby may not even display any symptoms.

In adults, if infection continues for an extended period of time, chronic toxoplasmosis can cause an inflammation of the eyes called retinochoroiditis, which can lead to blindness, severe yellowing of the skin and whites of the eyes (**jaundice**), easy bruising, and convulsions.

Adults with weakened immune systems have a high risk of developing cerebral toxoplasmosis, including inflammation of the brain (encephalitis), one–sided weakness or numbness, mood and personality changes, vision disturbances, **muscle spasms**, and severe headaches. If untreated, cerebral toxoplasmosis can lead to **coma** and death. This form of encephalitis is the second most common AIDS–related nervous system infection that takes advantage of a person's weakened immune system (opportunistic infection).

Diagnosis

A diagnosis of toxoplasmosis is made based on clinical signs and supporting laboratory results, including visualization of the protozoa in body tissue or **isolation** in animals and blood tests. Laboratory tests for toxoplasmosis are designed to detect increased amounts of a protein or antibody produced in response to infection with the toxoplasmosis organism. Antibody levels can be elevated for years, however, without active disease.

Treatment

Most individuals who contract toxoplasmosis do not require treatment because their immune systems are able to control the disease. Symptoms are not usually present. Mild symptoms may be relieved by taking over–the–counter medications, such as **acetaminophen** (Tylenol) and ibuprofen (Motrin, Advil). **Sore throat** lozenges and rest may also ease the symptoms.

WWW.BOOKBAZ.IR

Although the treatment of women infected with toxoplasmosis during pregnancy is controversial, most physicians feel that treatment is justified. Transmission of toxoplasmosis from the mother to the fetus may be prevented if the mother takes the antibiotic spiramycin. Later in a pregnancy, if the fetus has contracted the disease, treatment with the antibiotic pyrimethamine (Daraprim, Fansidar) or **sulfonamides** may be effective. Babies born with toxoplasmosis who show symptoms of the disease may be treated with pyrimethamine, the sulfa drug sulfadiazine (Microsulfon), and folinic acid (an active form of **folic acid**).

AIDS patients who have not been infected may be given a drug called TMP/SMX (Bactrim or Septra) to prevent toxoplasmosis infection. To treat cases of toxoplasmosis in immunocompromised AIDS patients, a combination of pyrimethamine and a sulfa–based drug, either sulfadiazine or clindamycin (Cleocin), have been used together and can be effective in treating this disease. Other antibiotic combinations and dosing schedules are still being investigated. Physicians have reported success in alleviating symptoms by using trimethoprim–sulfamethoxazole (Proloprim or Trimpex) or dapsone (DDS) plus pyrimethamine. These drugs can produce side effects, such as allergic reaction, **itching**, **rashes**, and nausea, and patients must be monitored closely.

Prognosis

Prognosis is poor when congenital toxoplasmosis is acquired during the first three months of pregnancy. Afflicted children die in infancy or have damage to their central nervous systems that can result in physical and intellectual disabilities. Infection later in pregnancy usually results in only mild symptoms, if any. The prognosis for acquired toxoplasmosis in adults with strong immune systems is excellent. The disease often disappears by itself after several weeks. However, the prognosis for immunodeficient patients is not as positive. These patients often relapse when treatment is stopped. The disease can be fatal to immunocompromised patients, especially patients with AIDS, and particularly if not treated. As a result, immunocompromised patients are typically placed on anti–toxoplasmosis drugs for the rest of their lives.

Prevention

There are no drugs that can eliminate *T. gondii* cysts in animal or human tissues. Humans can reduce their risks of developing toxoplasmosis by practicing the following:

- freezing (to 10.4°F/–12°C) and cooking foods to an internal temperature of 152°F/67°C will kill the cyst
- practicing sanitary kitchen techniques, such as washing utensils and cutting boards that come into contact with raw meat
- keeping pregnant women and children away from household cats and cat litter
- disposing of cat feces daily, because the oocysts do not become infective until after 24 hours
- helping cats to remain free of infection by feeding them dry, canned, or boiled food and by discouraging hunting and scavenging
- washing hands after outdoor activities involving soil contact and wearing gloves when gardening

Trabeculectomy

Definition

Trabeculectomy is a surgical procedure that removes part of the trabeculum in the eye to relieve pressure caused by **glaucoma**.

KEY TERMS

Cornea—Transparent film that covers the iris and pupil.

Iris—Colored part of the eye that is suspended in aqueous humor and perforated by the pupil.

Sclera—White, outer coating of the eyeball.

Trabeculoplasty—Laser surgery that creates perforations in the trabeculum, to drain built up aqueous humor and relieve pressure.

Trabeculum—Tissue that is a drainage point for aqueous humor in the eye.

Purpose

Glaucoma is a disease that injures the optic nerve, causing progressive loss of vision. Presently, glaucoma is a major cause of blindness in the United States If caught early, glaucoma-related blindness is easily prevented. However, since it does not produce symptoms until late in its cycle, periodic tests for the disease are necessary.

Glaucoma is usually associated with an increase in the pressure inside the eye. This increase occurs in front of the iris in a fluid called the aqueous humor. Aqueous humor is supposed to exit through tiny channels between the iris and the cornea, in an area called the trabeculum. When the trabeculum is blocked, pressure from the build up of aqueous humor either increases rapidly with considerable **pain** and redness, or, as in most cases, the pressure builds slowly with no symptoms until much of the vision is lost. Trabeculectomy is the last treatment employed for either type of glaucoma. It is used only after medications and laser trabeculoplasty (less invasive procedure that uses a laser to open the blocked trabeculum) have failed to alleviate the pressure.

Description

A trabeculectomy involves removing a tiny piece of the eyeball right at the place where the cornea connects to the sclera (the white part), and creating a flap to allow fluid to escape the anterior chamber without deflating the eye. Along with that tiny piece of cornea and sclera comes a piece of the iris. The whole area is called the trabeculum. Fluid can then flow out onto the surface of the eye and be absorbed by the conjunctiva, the transparent membrane that lines the sclera and the eyelids. Sometimes, an additional piece is taken out of the iris so that anterior chamber fluid can also flow backward into the vitreous part of the eye. This procedure is called an iridectomy.

Preparation

The procedure and its benefits and possible complications are fully explained. Antiglaucoma drugs are prescribed before surgery. Added pressure on the eye caused from coughing or sneezing should be avoided.

Aftercare

Eye drops, and perhaps patching, will be needed until the eye is healed. The pressure inside the eye will still be monitored. Immediately following the procedure, the patient may experience blurred vision.

Risks

Infection and bleeding are risks of any surgery. Scarring can cause the drainage to stop. A third of patients with trabeculectomies will develop **cataracts**.

Tracheoesophageal fistula

Definition

Tracheoesophageal **fistula** (TEF) is commonly a birth defect, with the trachea connected to the esophagus. In most cases, the esophagus is discontinuous, causing immediate feeding difficulties. TEFs may develop in adult life, secondary to the invasion of cancer in the area. In addition, TEFs may be deliberately constructed with surgery to aid talking in a patient who has the larynx removed (a **laryngectomy**).

Description

The trachea, or windpipe, carries air to the lungs. The esophagus carries food to the stomach. Sometimes during development, these two tubes do not separate completely, but remain connected by a short passage. When this happens, air enters the gastrointestinal system, causing the bowels to distend, and mucus is breathed into the lungs causing aspiration **pneumonia** and breathing problems.

WWW.BOOKBAZ.IR

Most tracheoesophageal fistulas are diagnosed when a child is born. There are three types. In 85–90% of tracheoesophageal fistulas, the top part of the esophagus ends in a blind sac, and the lower part inserts into the trachea. In the second type, the upper part of the esophagus is connected directly to the trachea, while the lower part ends in a pouch. In a rare type of fistula called an H type, both the esophagus and trachea are complete, but they are connected. This is the most difficult type of tracheoesophageal fistula to diagnose, because both eating and breathing are possible.

Causes and symptoms

Tracheoesophageal fistulas arise as a developmental abnormality. At birth, the infant has difficulty swallowing. Eating produces severe coughing spells that interfere with breathing. Aspiration pneumonia can develop from fluid breathed into the lungs.

Small H type fistulas may go undiagnosed until later in life. Symptoms of an H type fistula include frequent pulmonary infections and bouts of abdominal bloating.

Diagnosis

Diagnosis that the esophagus is interrupted is confirmed by the inability to insert a nasogastric suction tube into the stomach. The exact type and location of the fistula can be determined using a radiopaque catheter, which allows pictures to be taken of the esophagus. X rays may show air in the bowels. **Endoscopy** often fails to locate the fistula if it is small.

Treatment

Babies with all but H type fistulas are unlikely to survive without surgical separation and repair of the trachea and the esophagus. Surgery cannot always be performed immediately because of **prematurity**, the presence of other **birth defects**, or complications from aspiration pneumonia. It is usually done at a hospital that has special facilities for treating seriously ill newborns.

While awaiting surgery, the infant's condition is stabilized. Preoperative care concentrates on avoiding aspiration pneumonia and includes:

- elevating the head to avoid reflux and aspiration of the stomach contents
- using a suction catheter to continuously remove mucus and saliva that could be inhaled
- when necessary, placement of a gastrostomy tube
- withholding feeding by mouth

KEY TERMS

Endoscopy—A procedure in which an instrument containing a camera and a light source is inserted into the gastrointestinal tract so that the physician can visually inspect the gastrointestinal system.

Gastrostomy tube—Stomach tube for feeding.

Laryngectomy—Surgical removal of the larynx to treat cancer.

When surgery is performed, the esophagus is reconnected to make it continuous and separate from the trachea. If the two ends of the esophagus are too far apart to be reattached, a piece of tissue from the large intestine is used to join the parts.

Prognosis

Infants who have tracheoesophageal fistula often have other birth defects that affect their recovery. Even when the esophagus is successfully separated and reattached, many infants have difficulty swallowing, because the contractility of the esophagus is impaired. Infants may also have problems with gastroesophageal reflux, in which the acidic contents of the stomach back up into the bottom of the esophagus and cause **ulcers** and scarring.

Prevention

Tracheoesophageal fistulas are not preventable birth defects.

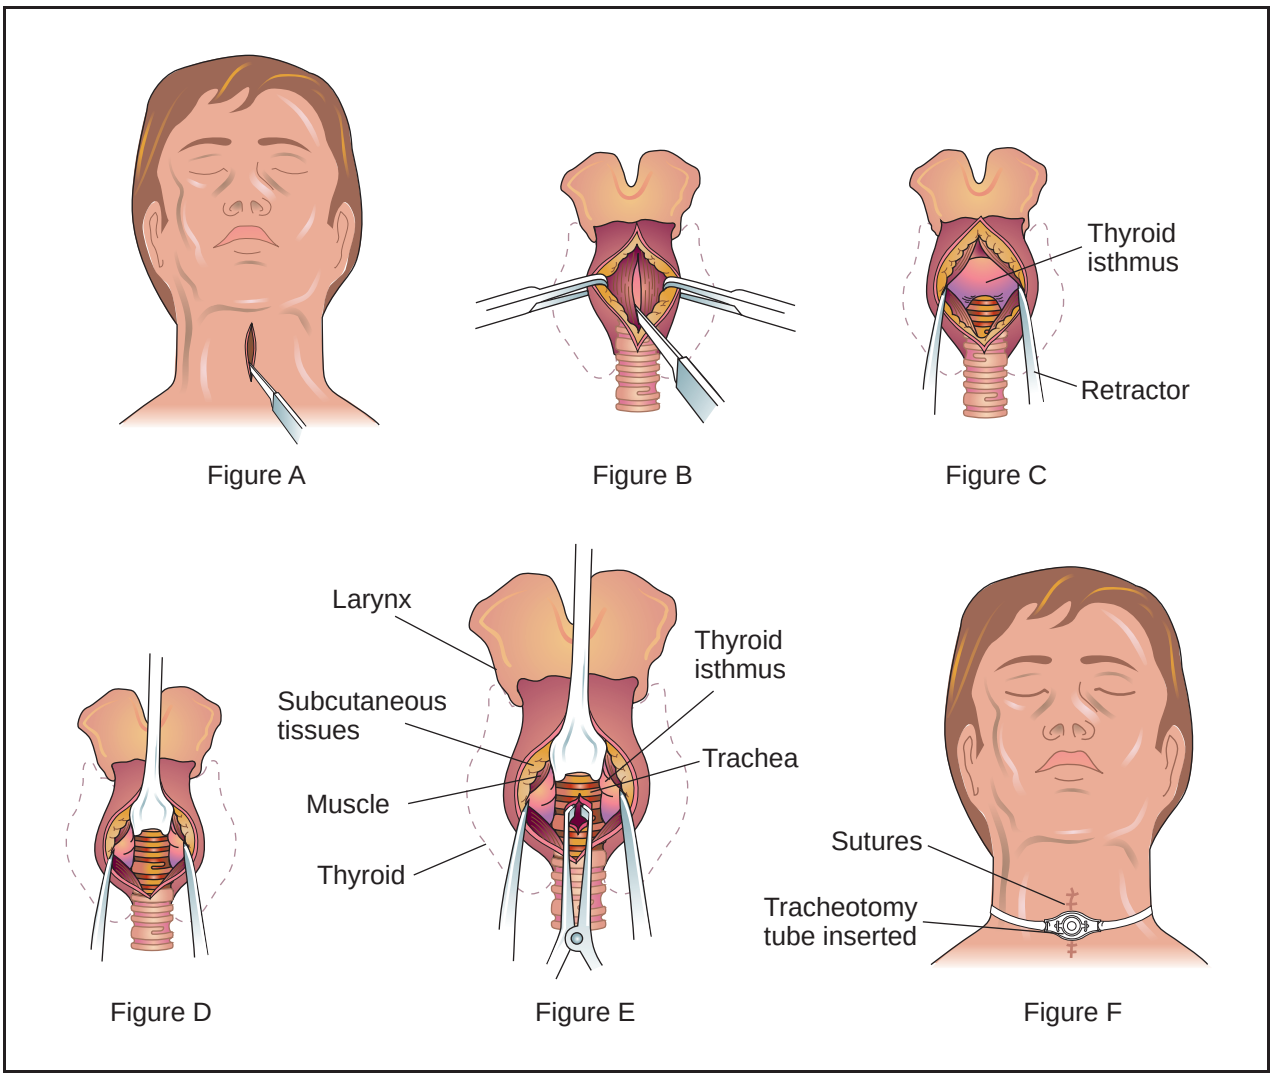
Tracheostomy *see* **Tracheotomy**

Tracheotomy

Definition

A tracheotomy is a surgical procedure that opens up the windpipe (trachea). It is performed in emergency situations, in the operating room, or at bedside



Tracheotomy is a surgical procedure in which an opening is made in the windpipe or trachea. The physician or surgeon will follow these steps in performing this procedure: Figure A: A vertical incision is made through the skin. Figure B: Another incision is made through the subcutaneous tissues and muscles of the neck. Figure C: The neck muscles are separated using retractors. Figure D: The thyroid isthmus is either cut or retracted. Figure E: The surgeon identifies the rings of cartilage that make up the trachea and cuts into the walls. of critically ill patients. The term tracheostomy is sometimes used interchangeably with tracheotomy. Strictly speaking, however, tracheostomy usually refers to the opening itself while a tracheotomy is the actual operation.

Purpose

A tracheotomy is performed if enough air is not getting to the lungs, if the person cannot breathe without help, or is having problems with mucus and other secretions getting into the windpipe because of difficulty swallowing. There are many reasons why air cannot get to the lungs. The windpipe may be blocked by a swelling; by a severe injury to the neck, nose, or mouth; by a large foreign object; by **paralysis** of the throat muscles; or by a tumor. The patient may be in a **coma**, or need a ventilator to pump air into the lungs for a long period of time.

Demographics

Emergency tracheotomies are performed as needed in any person requiring one.

WWW.BOOKBAZ.IR

KEY TERMS

Cartilage—A tough, fibrous connective tissue that forms various parts of the body, including the trachea and larynx.

Cricothyroidotomy—An emergency tracheotomy that consists of a cut through the cricothyroid membrane to open the patient's airway as fast as possible.

Larynx—A structure made of cartilage and muscle that connects the back of the throat with the trachea. The larynx contains the vocal cords.

Trachea—The tube that leads from the larynx or voice box to two major air passages that bring oxygen to each lung. The trachea is sometimes called the windpipe.

Ventilator—A machine that helps patients to breathe. It is sometimes called a respirator.

Description

Emergency tracheotomy

There are two different procedures that are called tracheotomies. The first is done only in emergency situations and can be performed quite rapidly. The emergency room physician or surgeon makes a cut in a thin part of the voice box (larynx) called the cricothyroid membrane. A tube is inserted and connected to an oxygen bag. This emergency procedure is sometimes called a cricothyroidotomy.

Surgical tracheotomy

The second type of tracheotomy takes more time and is usually done in an operating room. The surgeon first makes a cut (incision) in the skin of the neck that lies over the trachea. This incision is in the lower part of the neck between the Adam's apple and top of the breastbone. The neck muscles are separated and the thyroid gland, which overlies the trachea, is usually cut down the middle. The surgeon identifies the rings of cartilage that make up the trachea and cuts into the tough walls. A metal or plastic tube, called a tracheotomy tube, is inserted through the opening. This tube acts like a windpipe and allows the person to breathe. Oxygen or a mechanical ventilator may be hooked up to the tube to bring oxygen to the lungs. A dressing is placed around the opening. Tape or stitches (sutures) are used to hold the tube in place.

After a nonemergency tracheotomy, the patient usually stays in the hospital for three to five days, unless there is a complicating condition. It takes about two weeks to recover fully from the surgery.

Diagnosis/Preparation

Emergency tracheotomy

In the emergency tracheotomy, there is no time to explain the procedure or the need for it to the patient. The patient is placed on his or her back with face upward (supine), with a rolled-up towel between the shoulders. This positioning of the patient makes it easier for the doctor to feel and see the structures in the throat. A local anesthetic is injected across the cricothyroid membrane.

Nonemergency tracheotomy

In a nonemergency tracheotomy, there is time for the doctor to discuss the surgery with the patient, to explain what will happen and why it is needed. The patient is then put under general **anesthesia**. The neck area and chest are then disinfected and surgical drapes are placed over the area, setting up a sterile surgical field.

Aftercare

Postoperative care

A chest x ray is often taken, especially in children, to check whether the tube has become displaced or if complications have occurred. The doctor may prescribe **antibiotics** to reduce the risk of infection. If the patient can breathe without a ventilator, the room is humidified; otherwise, if the tracheotomy tube is to remain in place, the air entering the tube from a ventilator is humidified. During the hospital stay, the patient and his or her family members will learn how to care for the tracheotomy tube, including suctioning and clearing it. Secretions are removed by passing a smaller tube (catheter) into the tracheotomy tube.

It takes most patients several days to adjust to breathing through the tracheotomy tube. At first, it will be hard even to make sounds. If the tube allows some air to escape and pass over the vocal cords, then the patient may be able to speak by holding a finger over the tube. Special tracheostomy tubes are also available that facilitate speech.

The tube will be removed if the tracheotomy is temporary. Then the wound will heal quickly and only a small scar may remain. If the tracheotomy is permanent, the hole stays open and, if it is no longer needed, it will be surgically closed.

Home care

After the patient is discharged, he or she will need help at home to manage the tracheotomy tube. Warm compresses can be used to relieve **pain** at the incision site. The patient is advised to keep the area dry. It is recommended that the patient wear a loose scarf over the opening when going outside. He or she should also avoid contact with water, food particles, and powdery substances that could enter the opening and cause serious breathing problems. The doctor may prescribe pain medication and antibiotics to minimize the risk of infections. If the tube is to be kept in place permanently, the patient can be referred to a speech therapist in order to learn to speak with the tube in place. The tracheotomy tube may be replaced 4–10 days after surgery.

Patients are encouraged to go about most of their normal activities once they leave the hospital. Vigorous activity is restricted for about six weeks. If the tracheotomy is permanent, further surgery may be needed to widen the opening, which narrows with time.

Risks

Immediate risks

There are several short-term risks associated with tracheotomies. Severe bleeding is one possible complication. The voice box or esophagus may be damaged during surgery. Air may become trapped in the surrounding tissues or the lung may collapse. The tracheotomy tube can be blocked by **blood clots**, mucus, or the pressure of the airway walls. Blockages can be prevented by suctioning, humidifying the air, and selecting the appropriate tracheotomy tube. Serious infections are rare.

Long-term risks

Over time, other complications may develop following a tracheotomy. The windpipe itself may become damaged for a number of reasons, including pressure from the tube, infectious bacteria that forms scar tissue, or friction from a tube that moves too much. Sometimes the opening does not close on its own after the tube is removed. This risk is higher in tracheotomies with tubes remaining in place for 16 weeks or longer. In these cases, the wound is surgically closed. Increased secretions may occur in patients with tracheostomies, which require more frequent suctioning.

High-risk groups

The risks associated with tracheotomies are higher in the following groups of patients:

- children, especially newborns and infants
- smokers
- alcoholics
- obese adults
- persons over 60
- persons with chronic diseases or respiratory infections
- persons taking muscle relaxants, sleeping medications, tranquilizers, or cortisone

Results

Normal results include uncomplicated healing of the incision and successful maintenance of long-term tube placement.

Morbidity and mortality rates

The overall risk of death from a tracheotomy is less than 5%.

Alternatives

For most patients, there is no alternative to emergency tracheotomy. Some patients with pre-existing neuromuscular disease (such as ALS or **muscular dystrophy**) can be sucessfully managed with emergency noninvasive ventilation via a face mask, rather than with tracheotomy. Patients who receive nonemergency tracheotomy in preparation for mechanical ventilation may often be managed instead with noninvasive ventilation, with proper planning and education on the part of the patient, caregiver, and medical staff.

Trachoma

Definition

Trachoma, which is also called granular **conjunctivitis** or Egyptian ophthalmia, is a contagious, chronic inflammation of the mucous membranes of the eyes, caused by *Chlamydia trachomatis*. It is characterized by swelling of the eyelids, sensitivity to light, and eventual scarring of the conjunctivae and corneas of the eyes.

Description

Trachoma is a major cause of blindness in the world. It is found in the Far East, as well as countries with desert climates. In the United States, it is most common among certain Native Americans and in parts of Appalachia. The infection is highly contagious in its early stages. Blindness results from recurrent untreated infections.

The conjunctiva is the clear mucous membrane that lines the inside of the eyelid and covers the white part (sclera) of the eye. Conjunctivitis is an inflammation of the conjunctiva.

Causes and symptoms

Trachoma is caused by *C. trachomatis*, a parasitic organism closely related to bacteria. It is transmitted by insects, by hand-to-eye contact, or by the sharing of infected handkerchiefs or towels. The incubation period is about a week.

The early symptoms of trachoma include the development of follicles (small sacs) on the conjunctivae of the upper eyelids, **pain**, swollen eyelids, a discharge, tearing, and sensitivity to light. If the infection is not treated, the follicles develop into large yellow or gray pimples, and small blood vessels develop inside the cornea. In most cases, both eyes are infected.

A close-up of a human eye with trachoma. Trachoma is caused by *Chlamydia trahomatis* and commonly results in blindness if left untreated. *(Custom Medical Stock Photo, Inc.)*

Repeated infections eventually lead to contraction and turning-in of the eyelids, scarring of the corneas and conjunctivae, eventual blockage of the tear ducts, and blindness.

Diagnosis

Diagnosis is based on a combination of the patient's history (especially living or traveling in areas with high rates of trachoma) and examination of the eyes. The doctor will look for the presence of follicles or scarring. He or she will take a small sample of cells from the patient's conjunctivae and examine them, following a procedure called Giemsa staining, to confirm the diagnosis.

Treatment

Treatment of early-stage trachoma consists of four to six weeks of antibiotic treatment with tetracycline, erythromycin, or **sulfonamides**. **Antibiotics** should be given without waiting for laboratory test results. Treatment may combine oral medication with antibiotic ointment applied directly to the eyes. A single-dose treatment with azithromycin is an alternative method. **Tetracyclines** should not be given to pregnant women or children below the age of seven years.

Patients with complications from untreated or repeated infections are treated surgically. Surgery can be used for **corneal transplantation** or to correct eyelid deformities.

Prognosis

The prognosis for full recovery is excellent if the patient is treated promptly. If the infection has progressed to the stage of follicle development, prevention of blindness depends on the severity of the follicles, the presence of additional bacterial infections, and the development of scarring.

Prevention

There are vaccines available that offer temporary protection against trachoma, but there is no permanent immunization. Prevention depends upon good hygiene and **public health** measures:

- Seek treatment immediately if a child shows signs of eye infection, and minimize his or her contact with other children.

KEY TERMS

Conjunctivitis—Inflammation of the conjunctivae, which are the mucous membranes covering the white part of the eyeball (sclera) and lining the inside of the eyelids.

Cornea—The transparent front part of the eye that allows light to enter.

Ophthalmia—Inflammation of the eye. Usually severe and affecting the conjunctiva. Trachoma is sometimes called Egyptian ophthalmia.

- Teach children to wash hands carefully before touching their eyes.
- Protect children from flies or gnats that settle around the eyes.
- If someone has trachoma (or any eye infection), do not share towels, pillowcases, etc; wash items well.
- If medications are prescribed, follow the doctor's instructions carefully.

Traction

Definition

Traction is the use of a pulling force to treat muscle and skeleton disorders.

Purpose

Traction is usually applied to the arms and legs, the neck, the backbone, or the pelvis. It is used to treat **fractures**, **dislocations**, and long-duration **muscle spasms**, and to prevent or correct deformities. Traction can either be short-term, as at an accident scene, or long-term, when it is used in a hospital setting.

Traction serves several purposes:

- it aligns the ends of a fracture by pulling the limb into a straight position
- it ends muscle spasm
- it relieves pain
- it takes the pressure off the bone ends by relaxing the muscle

There are two main types of traction: skin traction and skeletal traction. Within these types, many specialized forms of traction have been developed to address problems in particular parts of the body. The application of traction is an exacting technique that requires training and experience, since incorrectly applied traction can cause harm.

Positioning the extremity so that the angle of pull brings the ends of the fracture together is essential. Elaborate methods of weights, counterweights, and pulleys have been developed to provide the appropriate force while keeping the bones aligned and preventing muscle spasm. The patient's age, weight, and medical condition are all taken into account when deciding on the type and degree of traction.

Precautions

People who have skin disorders or who are allergic to tape should not undergo skin traction, because the application of traction will aggravate their condition. Likewise, circulatory disorders or **varicose veins** can be aggravated by skin traction. People with an inflammation of the bone (**osteomyelitis**) should not undergo skeletal traction.

Description

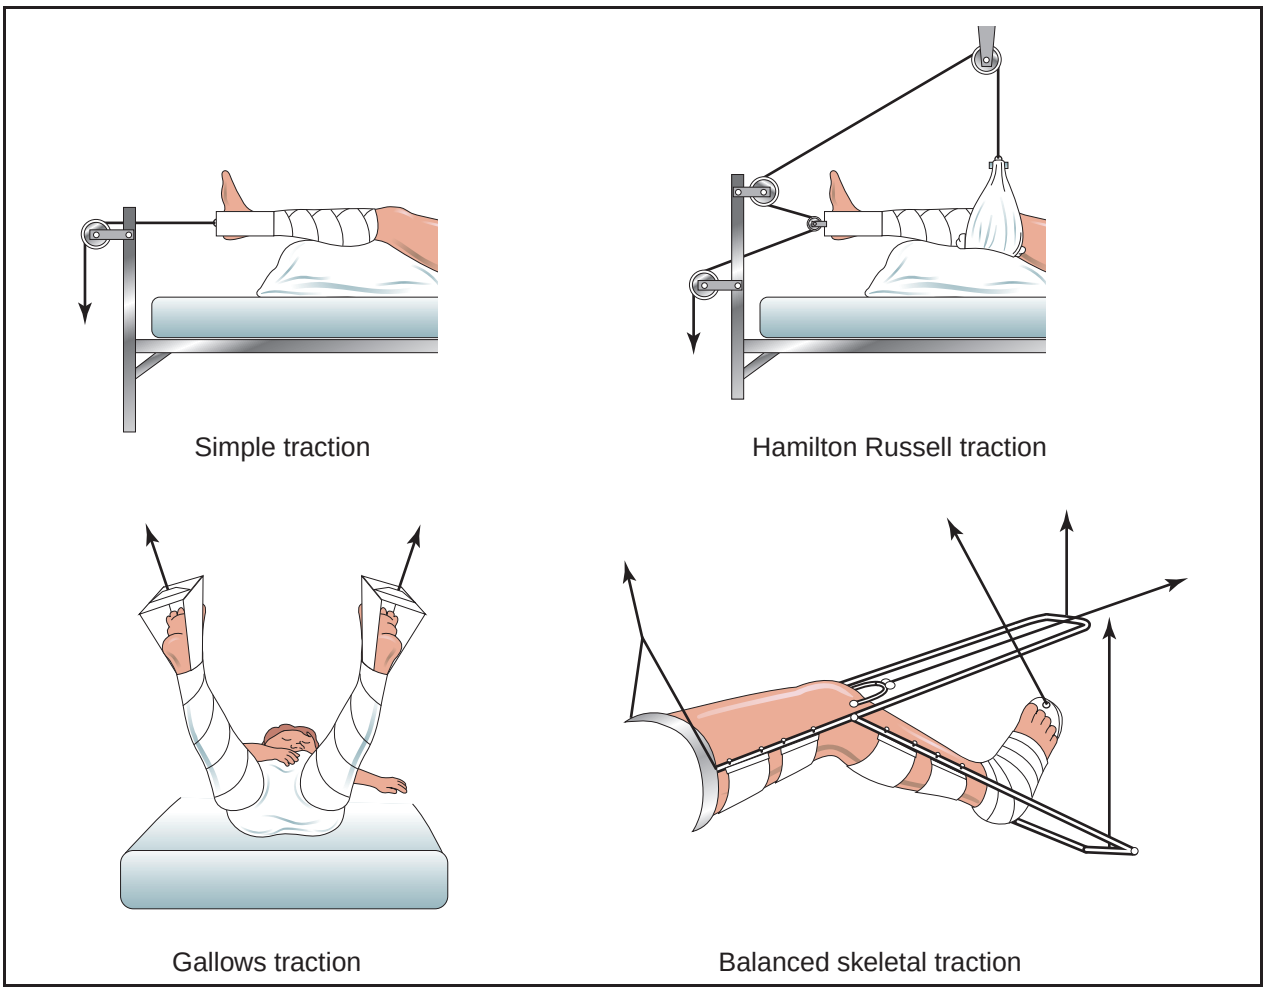
Skin traction

Skin traction uses 5–7 lb. (2.3–3.2 kg) weights attached to the skin to indirectly apply the necessary pulling force on the bone. If traction is temporary, or if only a light or discontinuous force is needed, then skin traction is the preferred treatment. Because the procedure is not invasive, it is usually performed in a hospital bed.

Weights are attached either through adhesive or nonadhesive tape, or with straps, boots, or cuffs. Care must be taken to keep the straps or tape loose enough to prevent swelling and allow good circulation to the part of the limb beyond the spot where the traction is applied. The amount of weight that can be applied through skin traction is limited because excessive weight will irritate the skin and cause it to slough off.

Specialized forms of skin traction have been developed to address specific problems. Dunlop's traction is used on children with certain fractures of the upper arm, when the arm must be kept in a flexed position to prevent problems with the circulation and

WWW.BOOKBAZ.IR



Traction refers to the use of a pulling force and special devices, such as a cast or splint, to treat muscle and skeletal disorders. The illustration above features several commonly used forms of traction. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

nerves around the elbow. Pelvic traction is applied to the lower spine, with a belt around the waist. Buck's skin traction is used to treat **knee injuries** other than fractures. The purpose of this traction is to stabilize the knee and reduce muscle spasm.

Skeletal traction

Skeletal traction is performed when more pulling force is needed than can be withstood by skin traction; or when the part of the body needing traction is positioned so that skin traction is impossible. Skeletal traction uses weights of 25-40 lb.

Skeletal traction requires the placement of tongs, pins, or screws into the bone so that the weight is applied directly to the bone. This is an invasive procedure that is done in an operating room under general, regional, or local **anesthesia**.

Correct placement of the pins is essential to the success of the traction. The pin can be kept in place several months, and must be kept clean to prevent infection. Once the hardware is in place, pulleys and weights are attached to wires to provide the proper pull and alignment on the affected part.

Specialized forms of skeletal traction include cervical traction used for fractures of the neck vertebrae; overhead arm traction used for certain types of upper arm fractures; and tibia pin traction used for some fractures of the femur, hip, or pelvis.

Preparation

X rays are done prior to the application of both forms of traction, and may be repeated during treatment to assure that the affected parts are staying in alignment and healing properly. Since the insertion of

the anchoring devices in skeletal traction is a surgical procedure, standard preoperative blood and urine testing are done, and the patient may meet with an anesthesiologist to discuss any health conditions that might affect the administration of anesthesia.

Aftercare

Aftercare for skin traction involves making sure the limb stays aligned, and caring for the skin so that it does not become sore and irritated. The patient should also be alert to any swelling or tingling in the limb that would suggest that the limb has been wrapped too tightly.

Aftercare for skeletal traction is more complex. The patient is likely to be immobile for an extended period. Deep breathing exercises are taught so that respiratory function is maintained during this time of little activity. Patients are also encouraged to do range-of-motion exercises with the unaffected parts of the body. The patient is taught how to use a trapeze (an overhead support bar) to shift on and off a bedpan, since it is not possible to get up to use the toilet. In serious injuries, traction may be continued for several months until healing is complete.

Risks

The main risks associated with skin traction are that the traction will be applied incorrectly and cause harm, or that the skin will become irritated. There are more risks associated with skeletal traction. Bone inflammation may occur in response to the introduction of foreign material into the body. Infection can occur at the pin sites. If caught early, infection can be treated with **antibiotics**, but if severe, it may require removal of the pin.

Both types of traction have complications associated with long periods of immobility. These include the development of bed sores, reduced respiratory function, urinary problems, and circulatory problems. Occasionally, fractures fail to heal. Being confined to traction for a long period can take an emotional toll on the patient.

Results

When correctly applied, traction generally produces very good, if slow, results.

Traditional Chinese medicine

Definition

Traditional Chinese medicine (TCM) is an ancient and still very vital holistic system of health and healing, based on the notion of harmony and balance, and employing the ideas of moderation and prevention.

Purpose

TCM is a complete system of healthcare with its own unique theories of anatomy, health, and treatment. It emphasizes diet and prevention and using **acupuncture**, herbal medicine, massage, and **exercise**; and focuses on stimulating the body's natural curative powers.

Precautions

In situations of severe **trauma**, TCM should not be substituted for contemporary modern trauma practice; it is most useful as an adjunct to the healing regimen. TCM is not the first line of treatment for bacterial infection or cancer, but may usefully complement contemporary medical treatment for those conditions.

Description

In theory and practice, traditional Chinese medicine is completely different from Western medicine, both in terms of considering how the human body works and how illness occurs and should be treated. As part of a continuing system that has been in use for thousands of years, it is still employed to treat over one-quarter of the world's population. Since the earliest Chinese physicians were also philosophers, their ways of viewing the world and human beings role in it affected their medicine. In TCM, both philosophically and medically, moderation in all things is advocated, as is living in harmony with nature and striving for balance in all things. Prevention is also a key goal of Chinese medicine, and much emphasis is placed on educating the patient to live responsibly. The Chinese physician also is more of an advisor than an authority; he or she believes in treating every patient differently, based on the notion that one does not treat the disease or condition but rather the individual patient. Thus two people with the same complaint may be treated entirely differently, if their constitutions and life situations are dissimilar. Disease is also considered to be evidence of the failure of preventive healthcare and a falling out of balance or harmony.

There is some confusion in the West about the fundamental philosophical principles upon which

WWW.BOOKBAZ.IR

TCM is based – such as the concept of yin and yang, the notion of five elements (wood, fire, earth, metal and water), and the concept of *chi*–yet each can be explained in a way that is understandable to Westerners.

Yin and yang describe the interdependent relationship of opposing but complementary forces believed to be necessary for a healthy life. Basically, the goal is to maintain a balance of yin and yang in all things.

The five elements, or five phase theory, is also grounded in the notion of harmony and balance. The concept of *chi*, which means something like "life force" or "energy," is perhaps most different from Western ideas. TCM asserts that *chi* is an invisible energy force that flows freely in a healthy person, but is weakened or blocked when a person is ill. Specifically, the illness is a result of the blockage, rather than the blockage being the result of the illness.

Besides these philosophical concepts that differ considerably from infection-based principles of medicine and health, the methods employed by TCM are also quite different. If allopathic Western practitioners could be described as interventionist and dependent on synthetic pharmaceuticals, TCM methods are mostly natural and noninvasive. For example, where Western physicians might employ surgery and **chemotherapy** or radiation for a cancer patient, a TCM physician might use acupuncture and dietary changes. TCM believes in "curing the root" of a disease and not merely in treating its symptoms.

Another major difference is how the patient is regarded. In Western medicine, patients with similar complaints or diseases, usually will receive virtually the same treatment. In TCM however, the physician treats the patient and not the condition, believing that identical diseases can have entirely different causes. In terms of the principles upon which it is based and the methods used, TCM is considered by many in the West to be a radically different healthcare system.

To some in the Western world, this very strangeness is the reason why it might be attractive. To others, tired of what they perceive as their physician's perfunctory, analytical, and sometimes cold manner, TCM offers a more humane, patient-oriented approach that encourages a high degree of practitioner-patient interaction and is not overly dependent on technology.

For example, during a consultation with a TCM practitioner, the patient will receive a considerable amount of time and attention. During the important first visit, the practitioner will conduct four types of examinations, all extremely observational and all quite different from what patients usually experience.

First, the practitioner will ask many questions, going beyond the typical patient history to inquire about such particulars as eating and bowel habits or sleep patterns. Next, the physician looks at the patient, observing his or her complexion and eyes, while also examining the tongue very closely, believing that it is a barometer of the body's health and that different areas of the tongue can reflect the functioning of different body organs. After observing, they listen to the patient's voice or **cough** and then smell his or her breath, body odor, urine, and even bowel movements. Finally, the practitioner touches the patient, palpating his or her abdomen and feeling the wrist to take up to six different pulses. It is through these different pulses that the well-trained practitioner can diagnose any problem with the flow of the all-important *chi*. Altogether, this essentially observational examination will lead the physician to diagnose or decide the patient's problem. This diagnosis is very different from one in contemporary Western medicine. No blood or urine samples are tested in a laboratory. The key to this technique lies in the experience and skill of the practitioner.

After making a diagnosis, the physician will suggest a course of treatment from one or all of the available TCM methods. These fall into four main categories: herbal medicine, acupuncture, dietary therapy, and massage and exercise. A typical TCM prescription consists of a complex variety of many different herbal and mineral ingredients. Chinese herbal remedies are intended to assist the body's own systems so that eventually the patient can stop taking them and never becomes dependent on them. Herbal formulas are usually given as teas, which differ according to the patient.

Other common techniques used in a TCM prescription are as follows:

- Acupuncture is based on the notion that the body's vital energy force, *chi*, travels through known channels or meridians. The acupuncturist inserts tiny, thin sterile needles at particular, selected points on the body to unblock or correct the flow of energy. These needles are hardly felt as they are inserted and are left in place for 15 to 20 minutes. Some patients report immediate improvement, others feel exhilarated, while some feel like sleeping. In some cases, patients say their condition worsens before it improves. No contemporary scientific explanation exists as to how or why acupuncture works.
- Moxibustion is a variation sometimes employed. Moxibustion is the slow burning on or over the

- Massage is often recommended, and a deep finger pressure technique known as acupressure is often used to promote the proper flow of *chi*.
- Diet is considered essential to good health, and what might be called "kitchen medicine" is just another aspect of herbalism. One example is DQ black bean soup that is traditionally eaten by women in China after childbirth and each menstrual cycle.
- Therapeutic exercises are sometimes prescribed as well. In both the exact and flowing movements of tai chi, and the breathing techniques of Qi Dong exercise is considered essential to relieving stress and promoting the smooth flow of *chi*.

As a system of total healthcare, TCM is prepared to deal with any physical or mental problem, condition, or disease. However, unlike Western medicine at its best, TCM is not able to render the kind of emergency crisis intervention that saves lives during physical traumas. Nonetheless, it works best at achieving its goal of practicing preventive medicine. It has proven effective in treating many types of aches and pains and in helping people with depression and **fatigue**, as well as circulation and digestive problems. Overall, its emphasis on good diet and exercise, as well as on individual responsibility and moderation in all things, suggest that it is grounded in fundamentally sound principles.

Risks

In the hands of a qualified practitioner, TCM is very safe. However, there is a small chance of not only getting an infection from acupuncture, but also that an existing infection could be spread to other parts of the body by increased blood flow and circulation.

Results

TCM seeks to harmonize and rebalance the entire human system rather than to treat just symptoms. Since proper internal balance is considered to be the key to human health, TCM strives to cure disease by restoring that balance and allowing the body to repair itself. Its continuing medical goal is to detect and correct abnormalities before they cause permanent physical damage.

Trager psychophysical integration

Definition

Trager psychophysical integration therapy, also known as the Tragerwork system of physical integration, is a combination of hands-on tissue mobilization, relaxation, and movement reeducation called Mentastics. The underlying principle of psychophysical integration is that clients learn to be lighter, easier, and freer by experiencing lightness, ease, and freedom of movement in their bodies.

The Trager method is a psychologically grounded physical approach to muscle relaxation, which is induced when a practitioner and patient achieve a state of mind called hook-up. Hook-up is described as a connection to a state of grace or a powerful and nourishing life force. It is the opposite of strain or effort.

Purpose

Psychophysical integration therapy has been helpful in relieving muscle discomfort in patients afflicted with **polio**, **muscular dystrophy**, Parkinson's disease,

WWW.BOOKBAZ.IR

multiple sclerosis, post-stroke **trauma**, and psychiatric disturbances. The therapy is useful in alleviating such chronic conditions as back and leg **pain**. Athletes may benefit from this system to increase resilience to injuries and to improve their mental attitudes. In addition, the Trager Institute maintains that Tragerwork helps clients achieve greater mental clarity through the release of "deep-seated physical and mental patterns."

Description

Origins

Psychophysical integration therapy began with Dr. Milton Trager (1908–1997), who earned a medical degree in midlife after working out his approach to healing chronic pain. Trager was born with a spinal deformity and overcame it through practicing a variety of athletic exercises. At the time that he discovered his approach to bodywork, he was training to become a boxer. His therapy came to public attention when Esalen Institute in California, the famous center of the human potential movement, invited him to give a demonstration of his technique during the mid-1970s. Trager abandoned his private medical practice in 1977 to devote full energy to the development and further understanding of psychophysical integration. The Trager Institute, which continues his work, was founded in 1980.

The Trager method consists of two parts, a passive aspect referred to as tablework and an active aspect called Mentastics, which is a self-care **exercise** program. Although the benefits of the Trager approach are said to be cumulative, practitioners and clients appear to be free to set their own schedules for a series of sessions. There is no minimum number of sessions that clients must agree to take.

Tablework

The tablework is performed on a comfortable padded table. Sessions last about 60–90 minutes. The practitioner moves the client in ways that he or she naturally moves, in such a way that he or she experiences how it feels to move effortlessly and freely on one's own. The movements resemble general mobilization techniques, and incorporate some manual, cervical, and lumbar **traction**. The goal of tablework is to allow the client "slowly to give up muscular and mental control and sink into a very deep state of relaxation not unlike that experienced in hypnosis."

Mentastics

Mentastics are free-flowing dance-like movements intended to increase the client's self-awareness, as well as providing tools to help the client move through and control chronic pain. The client is encouraged to "let go," which means that he or she is asked to begin a movement, then release muscle tension and allow the weight of the body part involved to complete the motion. By experiencing movement as something pleasurable and positive rather than painful or negative, clients begin to loosen up, learn new movements more easily, and even begin inventing their own. In the early stages of treatment, clients are advised to do Mentastic movements at home for 10–15-minute sessions, three times per day.

MILTON TRAGER (1909–1997)

Milton Trager was a medical doctor and a somatic educator, specializing in body learning. He was a contemporary of F. Matthias Alexander, Moshe Feldenkrais, and Ida Rolf.

As a young man in the 1920s, he occupied himself with gymnastics and boxing. Through his intensely physical pursuits, he arrived at his self-taught body learning theories. The techniques that he nurtured emphasized body control over strength, prowess, and endurance. For example, in striving to leap as high as possible, Trager focused his concentration on landing as softly as possible. He obtained a degree in physical medicine before serving in the military during World War II.

Upon his return, Trager funded his medical school education with his GI benefits. He established a private practice and spent the ensuing 50 years refining his body learning techniques and assisting afflicted individuals in the process. When Trager's father was stricken with sciatic pain, Trager learned to relieve the spasms by hand. In time he learned to alleviate the symptoms of polio victims and others who suffered from muscle spasms.

Trager established the Trager Institute in the 1970s to propagate the techniques that he had developed. By the year 2000, an estimated 2,000 students and practitioners had embraced the Trager Approach.

Trager lived with his wife, Emily, in Southern California at the time of his death in January 1997.

Preparations

Prior to a session of tablework, the client dresses for comfort, "with a minimum of swimwear or briefs," according to the Trager Institute. The client is also covered with a drape. No oils or lotions are used.

The practitioner prepares for the session by clearing his or her mind of everything but the client, until he or she achieves a state of hook-up. This attitude of

KEY TERMS

Hook-up—A state of effortless connection with a life-enhancing force. Trager practitioners enter a state of hook-up before working with clients in order to focus on their needs. Trager himself described hook-up as a meditative process of "becoming one with the energy force that surrounds all living things."

Mentastics—The active phase of Trager therapy. Mentastics are a form of movement reeducation in which clients learn to reexperience movement as pleasurable and positive.

Tablework—The passive phase of Trager therapy, in which the practitioner uses gentle and noninvasive movements to allow the client to relax deeply and experience physical movement as free and effortless.

"relaxed meditative awareness" on the part of the practitioner is one of the unique features of Tragerwork. It is described as allowing the therapist "to connect deeply with the recipient in an unforced way and enables the practitioner to perceive the slightest responses from the [client's] body."

Precautions

Because of the unusual sensitivity and heightened awareness that is associated with the practitioner's touch, pain should never result from tablework sessions. It is important for clients to alert the practitioner to any pain associated with either the tablework or the Mentastics program.

Although the movements used in Trager tablework are gentle and noninvasive, clients who have had recent injuries or surgery should wait to heal before undertaking a course of Tragerwork.

Side effects

The Trager method should not produce physical side effects when employed by a qualified practitioner. It is possible that some clients may have emotional reactions associated with the release of physical patterns acquired as a response to trauma, but such reactions are unusual.

Research and general acceptance

Tragerwork, like other forms of bodywork, has gained increasing acceptance as a form of treatment since the 1980s. In 2000 there were 1,200 certified psychophysical integration practitioners in 15 countries worldwide. The therapy has been reported as a commonly employed treatment for mainstream athletes. In addition, the National Institutes of Health lists psychophysical therapy as a mind-body form of complementary alternative medicine.

Trans fatty acids

Definition

Trans fatty acids are unsaturated fatty acids with at least one double bond in the *trans* configuration. Unsaturated fatty acids are derived metabolically from saturated fatty acids by the abstraction of pairs of hydrogen atoms from adjacent methylene groups. The removal of a pair of hydrogen atoms gives rise to a double bond. The remaining hydrogen atoms can either be on the same side of the fatty acid molecule, in which case the double bond has the *cis* geometrical configuration, or on opposite sides giving the *trans* configuration. *Trans* fatty acids occur naturally in small amounts in a few foods, however, the majority are formed during the partial hydrogenation of vegetable oils. This process converts vegetable oils into semi-solid fats for use in margarines, commercial cooking, and manufacturing processes. There is strong evidence that the consumption of *trans* fatty acids from industrial sources increases the risk of coronary **heart disease** (CHD).

Purpose

Whereas the presence of a *cis* bond in a fatty acid molecule affects the linearity of the fatty acid chain, making it fold back on itself, a *trans* bond has minimal effect on the conformation of the chain, making its physical properties more closely resemble those of a saturated fatty acid. The molecules of a *trans* fatty acid are able to pack together more closely than those of a *cis* isomer and this is reflected in differences in melting points. The melting point of the saturated fatty acid stearic acid (chain length of 18 carbons) is 157°F

WWW.BOOKBAZ.IR

(69.6°C), the melting point of oleic acid (chain length of 18 carbons with one *cis* bond) is 55.8°F (13.2°C), whereas the melting point of eladic acid, the *trans* isomer of oleic acid, is 111°F (44.0°C). For this reason, partially hydrogenated vegetable oils are used extensively by the food industry, as their high *trans* fatty acid content gives the oils a longer shelf life and an increased stability during deep-frying. Their semi-solidity can be customized to enhance the palatability of baked goods and sweets.

Description

Sources and consumption of trans *fatty acids in the United States diet*

The average consumption of industrially produced *trans* fatty acids in the United States is 2–3% of total calories consumed. The major sources of *trans* fatty acids in the American diet are deep-fried foods, bakery products, packaged snack foods, margarines, and crackers. Naturally occurring *trans* fatty acids are found in meats and dairy products from cows, sheep, and other ruminant animals; they are produced in the forestomach of the animal where polyunsaturated fatty acids of plant origin, such as linoleic acid and linolenic acid, can undergo partial or complete hydrogenation by the action of symbiotic anaerobic bacteria present in the ruminant stomach. These naturally occurring *trans* fatty acids are consumed in much smaller amounts, approximately 0.5% of total energy intake.

Trans *fatty acids from ruminant sources*

The predominant *trans* isomer in ruminant animals is vaccenic acid, from which conjugated linolenic acid (CLA) can be formed. It is possible to change the *trans* fatty acid content of ruminant products by altering the animals' feed although levels of *trans* fatty acids in meat and milk are already relatively low, between 1% and 8% of total fat content. With respect to CLA, it is considered desirable to increase levels in foods rather than to decrease levels. This is due to the suggested health benefits of CLA in humans, such as reduced insulin sensitivity and improved immune function, although the evidence remains inconclusive.

There is no association between intake of *trans* fatty acids from ruminant sources and risk of CHD and in fact some studies have shown non-significant trends towards an inverse association. The absence of a positive association of *trans* fatty acids from ruminant sources compared with from industrial sources may be due to lower levels of intake (less than 0.5% of total energy intake), different biological effects of different isomers, or the presence of other factors in meat and diary products that outweigh any effects of the small amount of *trans* fatty acids they contain. Further research in these areas is needed although it would seem that *trans* fatty acids from ruminant sources do not pose a threat to **public health**.

Precautions

The physiological effects of trans *fatty acids from industrial sources*

The main effects of *trans* fatty acids are on serum lipid levels. Numerous controlled dietary trials have been conducted to evaluate the effect of isocaloric replacement of saturated or *cis* unsaturated fatty acids with *trans* fatty acids. The data from many of these studies has been used in a number of large meta-analyses, all of which strongly indicate that compared with saturated or *cis* unsaturated fatty acids, the consumption of *trans* fatty acids raises levels of low density lipoprotein (LDL) **cholesterol**, reduces levels of high density lipoprotein (HDL) cholesterol and increases the ratio of total cholesterol to HDL cholesterol, all of which are powerful risk factors for CHD.

There is substantial evidence to show that *trans* fatty acids also promote systemic inflammation. In a large trial of women, greater intake of *trans* fatty acids was associated with increased activity of the tumour necrosis factor (TFN) system, a biomarker used to measure inflammation. Among those with a higher **body mass index** (BMI), a greater intake of *trans* fatty acids was also associated with other inflammatory substances. The presence of inflammation is an independent risk factor for atherosclerosis, sudden death from cardiac causes, **diabetes mellitus**, and **heart failure**. Thus, the inflammatory effects of *trans* fatty acids contribute further to overall CHD risk.

The risk to health of consuming *trans* fatty acids from industrial sources has been recognized and acknowledged by the United States government. The Food and Drug Administration (FDA) made it compulsory from 2006, for **nutrition** labels for all conventional foods and supplements to indicate the content of *trans* fatty acids. In addition, the Department of Agriculture has made a limited intake of *trans* fatty acids a key recommendation of the new food pyramid guidelines, following the recommendations of the **Dietary Guidelines** Advisory Committee that intake of *trans* fatty acids should be less than 1% of total energy. Furthermore, action is being taken at local levels; the New York City Department of Health and Mental Hygiene has asked 20,000 restaurants and 14,000 food suppliers to eliminate partially

hydrogenated oils from kitchens and to provide foods free from industrially produced *trans* fatty acids. Although the elimination of these *trans* fatty acids may be challenging, experience in other countries, such as Denmark, indicates that these fats can largely be replaced by *cis* unsaturated fats without increasing the cost or availability of foods.

Healthcare providers should advise consumers about how to minimize the intake of *trans* fatty acids, consumers should be able to recognize and avoid products containing *trans* fatty acids and restaurants and food manufacturers should use alternative fats in food production and preparation. These measures should ensure a reduction in *trans* fatty acid consumption and result in substantial health benefits particularly a reduction in the incidence of CHD.

Complications

Trans *fatty acid intake and risk of disease*

***TRANS* FATTY ACID INTAKE AND CHD.** On a per calorie basis, *trans* fatty acids increase the risk of CHD more than any other macronutrient, conferring a substantially increased risk even at low levels of consumption (1–3% of total energy intake). Even a small rise in energy intake from *trans* fatty acids can cause a large increase risk. A meta-analysis of four prospective cohort studies that included data from 140,000 subjects showed a 23% increase in CHD incidence when energy intake from *trans* fatty acids increased by just 2%. So dramatic is the impact of *trans* fatty acids on CHD risk, another study showed that the positive association between levels of *trans* fatty acids in adipose tissue (a biomarker for dietary intake) and CHD risk was diminished after 1996, when *trans* fatty acids were eliminated from margarines sold in Australia and the population's consumption levels decreased.

The potential benefits of reducing consumption of *trans* fatty acids from industrial sources on the incidence of CHD in the United States has been calculated. On the basis of predicted changes in total and HDL cholesterol, CHD events could be reduced by 3–6%. If the influence of *trans* fatty acids on other risk factors such as inflammatory effects is considered, CHD events could be reduced by 10–19% (equivalent to between 72,000 and 228,000 CHD events each year). This reduction could be even greater, if healthier *cis* unsaturated fatty acids, including **omega-3 fatty acids**, are used to replace *trans* fatty acids.

***TRANS* FATTY ACID INTAKE AND DIABETES.** The association between risk of diabetes and *trans* fatty acid intake is less clear. Three prospective studies have investigated this relationship and in two of the studies, consumption of *trans* fatty acids was not significantly associated with increased risk of diabetes. However, in a study of nearly 85,000 female nurses a strong positive association was found. The nurses were followed for 16 years, information of dietary intake was periodically updated and self-reported diabetes was validated. The conclusions of no association in the first two studies may be explained by the relatively low intake in one cohort of male health professionals (average intake of 1.3% energy).

Results

Parents should eliminate all sources of *trans* fatty acids from industrial sources from their children's **diets** as these have no intrinsic health value above their energy value. Their consumption is linked with considerable potential harm and no apparent benefit. As adverse effects are seen at even low levels of intake, between 1% and 3% of total energy (2–7 g per day for a person consuming 2,000 calories), it seems complete or near complete avoidance of *trans* fatty acids should be advised in order to minimize health risks.

Transcranial Doppler ultrasonography

Definition

Transcranial **Doppler ultrasonography** is a noninvasive method of analyzing blood flow in the brain.

Purpose

The blood that flows through the brain distributes nutrients to the brain and removes wastes. This flow maintains the high rate of metabolism necessary for the brain to function. Restrictions in blood flow may occur from vessel narrowing (stenosis), clot formation (thrombosis), blockage (**embolism**), or blood vessel rupture (hemorrhage). Lack of sufficient blood flow (ischemia) threatens brain tissue and may cause a **stroke**.

The flow of blood through the arteries in the brain can be analyzed using transcranial Doppler ultrasonography (TCD). TCD is a form of **ultrasound**, in which high frequency sound waves bounce off or pass through body tissues. While most other types of ultrasonography create images of the tissue being studied, the results of TCD are audible sounds that the examiner listens to and records.

Doppler ultrasonography uses what is called the Doppler effect to measure the rate and direction of blood flow in the vessels. Just as a siren's pitch sounds higher when its source is moving toward you and lower as it moves away, so too will ultrasound waves change pitch, or frequency, as they bounce off the red blood cells moving in the blood. It is these pitch changes that produce the audible sounds during the exam.

Changes in frequency can be used to measure both the direction and the speed of blood flow. Faster blood flow causes a greater change in frequency. Combined with other tests, this information can be used to locate restrictions in the blood vessels in the brain, and to track changes in blood flow over time. In this way, TCD gives valuable information about the site of a stroke and the patient's progress after a stroke. TCD is also used to evaluate the contraction of blood vessels that can occur if a blood vessel ruptures.

Precautions

Ultrasonography procedures are safe, noninvasive, and painless. No special precautions are necessary.

Description

TCD is done with either one or two probes placed against the skin. The examiner spreads a clear gel on the areas of the head where the probe will be placed. Usually, the probes are placed on the temple, on the base of the skull at the back of the neck, and over the closed eyelid. In these places, there is the least amount of thick protective bone and the sound waves can penetrate the best. The examiner adjusts the probe position and orientation to direct the sound waves

toward the blood vessels of interest. Finding the best approach may take some time. A compression test may be performed during the exam. In this test, the main artery in the neck (carotid artery) is briefly compressed, and changes in blood flow patterns are observed. A full TCD exam may last 30–45 minutes, and often longer in patients with disease.

Preparation

No special preparation is needed. The patient should remove **contact lenses**, and may wish to avoid the use of eye makeup, since the gel is likely to smear it.

Aftercare

The gel is washed off with soap and water. No other after care is needed.

Risks

TCD is noninvasive and has no risks. A compression test is occasionally, though very rarely, hazardous for a patient with narrowed arteries (atherosclerosis), since the increased pressure may dislodge a piece of the substance that causes the narrowing (plaque).

Results

TCD produces an audible sound that varies with the heartbeat. It also varies depending on the direction and rate of flow through the vessel being examined. Each of the vessels in the brain has a characteristic direction of flow, which can be detected by TCD. Flow rates are somewhat variable from person to person.

Abnormal results

Lack of flow indicates a vessel has been completely blocked (although absence of a signal may also be due to absorption of sound waves by bone). If blood flows in the wrong direction or alternates between normal and reverse flow, it may mean there is a blockage elsewhere. This happens because blood is rerouted due to abnormalities in pressure caused by the blockage.

If the speed of flow is increased, it may mean that blood is flowing through a restricted area that is just "upstream" from the probe. Intuitively, one might think that a restricted blood vessel would cause the speed of blood flow to slow down. However, the opposite is true. This is because the same amount of blood going through a narrower opening must go faster. Increased speed is also seen if a vessel is carrying rerouted blood.

Transesophageal echocardiography

Definition

Transesophageal **echocardiography** is a diagnostic test using an **ultrasound** device that is passed into the esophagus of the patient to create a clear image of the heart muscle and other parts of the heart. A tube with a device called a transducer is passed down into the patient's throat and into the esophagus (the food tube that connects the mouth to the stomach). The transducer directs ultrasound waves into the heart, and the reflected sound waves picked up by the transducer are translated into an image of the heart.

Purpose

Since the esophagus is right next to the heart, transesophageal echocardiography provides a very clear picture of the heart. It can provide information on the size of the heart, its pumping strength, and the location and extent of any damage to its tissues. It can detect abnormal tissue growth around the heart valves. It is also good at detecting abnormalities in the pattern of blood flow, such as the backward flow of blood through partly closed heart valves, known as regurgitation or insufficiency. It is especially useful in cases in which conventional echocardiography (a test where the transducer is kept on the patient's chest) cannot offer a good image, such as when the patient is obese or has a thick chest wall. It is useful for monitoring heart function during cardiac surgery and detecting **blood clots** in the left atrium of the heart.

Precautions

Patients should avoid consuming alcohol for a day or so before the procedure, since alcohol may amplify the effects of the sedative used with the procedure.

Description

Echocardiography creates an image of the heart using ultra-high-frequency sound waves—sound waves that are much too high in frequency to be heard by the human ear. The technique is very similar to ultrasound scanning commonly used to visualize the fetus during **pregnancy**.

A transesophageal echocardiography examination generally lasts 30–60 minutes. The patient is given a mild sedative and the back of the throat is sprayed with a local anesthetic, in order to suppress the gag reflex. Next, a special viewing tube called an endoscope, containing a tiny transducer, is passed through the mouth and into the esophagus. It is carefully moved until it is positioned directly next to the heart. Essentially a modified microphone, the transducer directs ultrasound waves into the heart, some of which get reflected (or "echoed") back to the transducer. Different tissues and blood all reflect ultrasound waves differently. These sound waves can be translated into a meaningful image of the heart, which is displayed on a monitor or recorded on paper or tape. The transducer may be moved several times during the test to help doctors get a better view of the heart.

Preparation

The patient may be given a mild sedative before the procedure, and an anesthetic is sprayed into the back of the throat in order to suppress the gag reflex.

Aftercare

After the test, it is important to refrain from eating or drinking until the gag reflex has returned—otherwise, the patient may accidentally inhale some of the food or beverage. If a sedative has been given, patients should not drive or operate heavy machinery for at least 10-12 hours. They should avoid consuming alcohol for a day or so, since alcohol may amplify the effect of the sedative.

Risks

Transesophageal echocardiography may cause gagging and discomfort when the transducer is passed down into the throat. Patients may also experience **sore throat** for a few days after the test. In rare cases, the procedure may cause bleeding or perforation of the esophagus or an inflammatory condition known as infective **endocarditis**. The patient may have an adverse reaction to the sedative or local anesthetic.

KEY TERMS

Endoscope—An instrument used to see and examine the inside of a body cavity or organ.

Gag reflex—A normal reflex consisting of elevation of the palate, retraction of the tongue, and contraction of the throat muscles.

Regurgitation—Backward flow of blood through a partly closed valve.

Transducer—A device that converts electrical signals into ultrasound waves and ultrasound waves back into electrical impulses.

Ultrasound—Sound waves at a frequency of 20,000 kHz, often used for diagnostic imaging.

Results

A normal transesophageal echocardiogram shows a normal heart structure and the normal flow of blood through the heart chambers and heart valves.

Abnormal results

A transesophageal echocardiogram may show a number of abnormalities in the structure and function of the heart, such as thickening of the wall of the heart muscle (especially the left ventricle). Other abnormalities can include blood leaking backward through the heart valves (regurgitation), or blood clots in the left atrium of the heart.

Transfusion

Definition

Transfusion is the process of transferring blood or blood components from a donor to a recipient.

Purpose

Transfusions are given to restore lost blood, to improve clotting time, and to improve the ability of the blood to deliver oxygen to the body's tissues. About 40,000 pints of donated blood are transfused each day in the United States.

In the United States, blood collection is strictly regulated by the U.S. Food and Drug Administration (FDA), which has rules for the collection, processing, storage, and transportation of blood and blood products. In addition, the American Red Cross, the American Association of Blood Banks (AABB), and most states have specific rules for the collection and processing of blood. The main purpose of regulation is to ensure the quality of transfused blood and to prevent the transmission of infectious diseases through donated blood. Before blood and blood products are used, they are extensively tested for such infectious agents as hepatitis and human **immunodeficiency** virus (HIV).

Demographics

In order to donate blood, an individual must be at least 17 years old, weigh at least 110 lb. (50 kg), and be in generally good health. The average blood donor is a white, married, college-educated male between the ages of 30 and 50, although the Red Cross states that 50% of their blood donors are male and 50% are female. Twenty-five percent of people receiving blood transfusions are over the age of 65, although the elderly constitute only 13% of the population. Fewer than 5% of Americans donate blood each year.

Description

Either whole blood or its components can be used for transfusion. Most blood collected from donors is broken down (fractionated) into components that are used to treat specific problems or diseases. Treating patients with fractionated blood is the most efficient way to use the blood supply.

Whole blood

Whole blood is used exactly as received from the donor. Blood components are parts of whole blood, such as red blood cells (RBCs), white blood cells (WBCs), plasma, platelets, clotting factors, and immunoglobulins. Whole blood is used only when needed or when fractionated components are not available, because too much whole blood can raise the recipient's blood pressure. Use of blood components is a more efficient way to use the blood supply, because blood that has been fractionated can be used to treat more than one person.

Whole blood is generally used when a person has lost a large amount of blood. Such blood loss can be caused by injury or surgical procedures. Whole blood is given to help restore the blood volume, which is essential for maintaining blood pressure. It is also given to ensure that the body's tissues are receiving enough oxygen. Whole blood is occasionally given when a required blood fraction is unavailable in isolated form.

Red blood cells

RBCs carry oxygen throughout the body. They pick up oxygen as they pass through the lungs, and give up oxygen to the other tissues of the body as they are pumped through the arteries and veins. When patients do not have enough RBCs to properly oxygenate their tissues, they can be given a transfusion with RBCs obtained from donors. This type of transfusion will increase the amount of oxygen carried to the tissues of the body. RBCs are recovered from whole blood after donation. They are then typed, removed from the watery blood plasma to minimize their volume (packed), and stored. RBCs are given to people with anemia (including **thalassemia**), whose bone marrow does not make enough RBCs, or who have other conditions that decrease the number of RBCs in the blood. Occasionally, RBCs from rare blood types are frozen. Once frozen, RBCs can survive for as long as ten years. Packed RBCs are given in the same manner as whole blood.

White blood cells

WBCs are another infection-fighting blood component. On rare occasions, WBCs are given by transfusion to treat life-threatening infections. Such transfusions are given when the WBC count is very low or when the patient's WBCs are not functioning normally. Most of the time, however, **antibiotics** are used in these cases.

Plasma

Plasma is the clear yellowish liquid portion of blood. It contains many useful proteins, especially clotting factors and immunoglobulins. After plasma or plasma factors are processed, they are usually frozen. Some plasma fractions are freeze-dried. These fractions include clotting factors I through XIII. Some people have an inherited disorder in which the body produces too little of the clotting factors VIII (**hemophilia** A) or IX (hemophilia B). Transfusions of

WWW.BOOKBAZ.IR

these clotting factors help to stop bleeding in people with hemophilia. Frozen plasma must be thawed before it is used; freeze-dried plasma must be mixed with liquid (reconstituted). In both cases, these blood fractions are usually small in volume and can be injected with a syringe and needle.

Platelets

Platelets are small disk-shaped structures in the blood that are essential for clotting. People who do not have enough platelets (a condition called **thrombocytopenia**) have bleeding problems. People who have lymphoma or leukemia and people who are receiving cancer therapy do not make enough platelets. Platelets have a very short shelf life; they must be used within five days of **blood donation**. After a unit of blood has been donated and processed, the platelets in it are packed into bags. A platelet transfusion is given in the same manner as whole blood.

Immunoglobulins

Immunoglobulins are the infection-fighting fractions in blood plasma. They are also known as **gamma globulin**, antibodies, and immune sera. Immunoglobulins are given to people who have difficulty fighting infections, especially people whose immune systems have been depressed by such diseases as **AIDS**. Immunoglobulins are also used to prevent **tetanus** after a cut has been contaminated, to treat animal bites when **rabies** is suspected, or to treat severe childhood diseases. Generally, the volume of immunoglobulins used is small, and it can be injected.

Transfusion process

Blood is collected from the donor by inserting a large needle into a vein in the arm, usually one of the larger veins near the inside of the elbow. A tourniquet is placed on the upper arm to increase the pressure in the arm veins, which makes the veins swell and become more accessible. Once the nurse or technician has identified a suitable vein, she or he sterilizes the area where the needle will be inserted by scrubbing the skin with a soap solution or an antiseptic that contains iodine. Sometimes both solutions are used. The donor lies on a bed or cot during the procedure, which usually takes 10–20 minutes. Generally, an 18-gauge needle is used. This size of needle fits easily into the veins and yet is large enough to allow blood to flow easily. Human blood will sometimes clot in a smaller needle and stop flowing. The donor's blood is collected in a sterile plastic bag that holds 1 pt. (450 mL). The bags contain an anticoagulant to prevent clotting and preservatives to keep the blood cells alive. A sample of the donor's blood is collected at the time of donation and tested for infectious diseases. The blood is not used until the test results confirm that it is safe. Properly handled and refrigerated, whole blood can last for 42 days.

The recipient of a transfusion is prepared in much the same way as the blood donor. The site for the needle insertion is carefully washed with a soap-based solution followed by an antiseptic containing iodine. The skin is then dried and the transfusion needle inserted into the vein. During the early stages of a transfusion, the recipient is monitored closely to detect any adverse reactions. If no signs of adverse reaction are evident, the patient is monitored occasionally for the duration of the transfusion period. Upon completion of the transfusion, a compress is placed over the needle insertion site to prevent extensive bleeding.

Blood typing

All donated blood is typed, which means that it is analyzed to determine which of several major and minor blood types (also called blood groups) it belongs. Blood types are genetically determined. The major types are classified by the ABO system. This system groups blood with reference to two substances in the red blood cells called antigen A and antigen B. The four ABO blood types are A, B, AB, and O. Type A blood has the A antigen, type B has the B antigen, type AB has both, and type O has neither. These four types of blood are further classified by the Rh factor. The Rh, or Rhesus factor, is also an antigen in the red blood cells. A person who has the Rh factor is Rh positive; a person who does not have the factor is Rh negative. If a person has red blood cells with both the B and the Rh antigens, that person is said to have a B positive (B+) blood type. Blood types determine which kinds of donated blood a patient can receive. Generally, patients are limited to receiving only blood of the exact same ABO and Rh type as their own. For example, a person with B+ blood can receive blood or blood cells only from another person with B+ blood. An exception is blood type O. Individuals with type O blood are called universal donors, because people of all blood types can accept their blood.

Blood can also be typed with reference to several other minor antigens, such as Kell, Kidd, Duffy, and Lewis. These minor antigens can become important when a patient has received many transfusions. These patients tend to build up an immune response to the minor blood groups that do not match their own. They may have an adverse reaction upon receiving a transfusion with a mismatched minor blood group. A third

group of antigens that may cause a reaction are residues from the donor's plasma attached to the RBCs. To eliminate this problem, the RBCs are rinsed to remove plasma residues. These rinsed cells are called washed RBCs.

Other transfusion procedures

Autologous transfusion is a procedure in which patients donate blood for their own use. Patients who are to undergo surgical procedures requiring a blood transfusion may choose to donate several units of blood ahead of time. The blood is stored at the hospital for the patient's exclusive use. Autologous donation assures that the blood type is an exact match. It also assures that no infection will be transmitted through the blood transfusion. Autologous donation accounts for 5% of blood use in the United States each year.

Directed donors are family or friends of the patient who needs a transfusion. Some people think that family and friends provide a safer source of blood than the general blood supply. Studies do not show that directed donor blood is any safer. Blood that is not used for the identified patient becomes part of the general blood supply.

Apheresis is a special procedure in which only certain specific components of a donor's blood are collected. The remaining blood fractions are returned to the donor. A special blood-processing instrument is used in apheresis. It fractionates the blood, saves the desired component, and pumps all the other components back into the donor. Because donors give only part of their blood, they can donate more frequently. For example, people can give almost ten times as many platelets by apheresis as they could give by donating whole blood. The donation process takes about one to two hours.

Preparation

The first step in blood donation is the taking of the donor's medical history. Blood donors are questioned about their general health, their lifestyle, and any medical conditions that might disqualify them. These conditions include hepatitis, AIDS, cancer, **heart disease**, **asthma**, **malaria**, bleeding disorders, and high blood pressure. Screening prevents people from donating who might transmit diseases or whose medical condition would place them at risk if they donated blood. Some geographical areas or communities have a high rate of hepatitis or AIDS. Blood collection in most of these areas has been discontinued indefinitely.

The blood pressure, temperature, and pulse of donors are taken to ensure that they are physically able to donate blood. One pint (450 mL) of blood is usually withdrawn, although it is possible to donate smaller amounts. The average adult male has 10–12 pt. (4.7–5.7 L) of blood in his body; the average adult female has 8–9 pt. (3.8–4.2 L) in hers. Within hours after donating, most people's bodies have replaced the fluid lost with the donated blood, which brings their blood volume back to normal. Replacement of the blood cells and platelets, however, can take several weeks. Pregnant women and people with low blood pressure or anemia should not donate blood or should limit the amount of blood they give. Generally, people are allowed to donate blood only once every two months. This restriction ensures the health of the donor and discourages people from selling their blood. The former practice of paying donors for blood has essentially stopped. Donors who sell blood tend to be at high risk for the transmission of blood-borne diseases.

Aftercare

Recipients of blood transfusion are monitored during and after the transfusion for signs of an adverse reaction. Blood donors are generally given fluids and light refreshments to prevent such possible side effects as **dizziness** and nausea. They are also asked to remain in the donation area for 15–20 minutes after giving blood to make sure that they are not likely to faint when they leave.

Risks

Risks for donors

For donors, the process of giving blood is very safe. Only sterile equipment is used and there is no chance of catching an infection from the equipment. There is a slight chance of infection at the puncture site if the skin is not properly cleaned before the collection needle is inserted. Some donors feel lightheaded when they sit up or stand for the first time after donating. Occasionally, a donor may faint. Donors are encouraged to drink plenty of liquids to replace the fluid lost with the donated blood. It is important to maintain the fluid volume of the blood so that the blood pressure will remain stable. Strenuous **exercise** should be avoided for the rest of the day. It is normal to feel some soreness or to find a small bluish bruise at the site of the needle insertion. Most donors have very slight symptoms or no symptoms at all after giving blood.

Risks for recipients

A number of precautions must be taken for transfusion recipients. Donated blood must be matched with the recipient's blood type, as incompatible blood types

WWW.BOOKBAZ.IR

can cause a serious adverse reaction (transfusion reaction). Blood is introduced slowly by gravity flow directly into the veins (intravenous infusion) so that medical personnel can observe the patient for signs of adverse reactions. People who have received many transfusions may develop an immune response to some factors in foreign blood cells. This immune reaction must be evaluated before the patient is given new blood. Some transfusion reactions can be avoided or controlled through premedication with medications like **steroids** and/or **antihistamines**.

Transfusion reactions include:

- Allergic reactions, in which some allergen in the donated blood reacts with antibodies in the recipient's blood. This can lead to itching, hives, or severe reactions involving respiratory distress.
- Acute hemolytic transfusion reaction is a severe and immediate reaction due to mismatch of donor and recipient blood type, in which the donated blood cells are rapidly destroyed by the recipient's immune system, leading to more severe symptoms such as fever, pain, and kidney failure.
- Delayed hemolytic transfusion reaction occurs some hours or days (up to almost a month) after a transfusion. Like an acute hemolytic reaction, the recipient's body produces antibodies that attack and destroy the donated red cells. Symptoms of this delayed response tend to be more mild than those of the acute reaction or may even go unnoticed, and they can only be diagnosed during blood testing. This variant is called delayed serologic transfusion reaction.
- Febrile non-hemolytic transfusion reaction is the most frequently encountered transfusion reaction. No hemolysis (RBC breakdown) takes place, but the patient experiences symptoms of fever and chills.
- Hypotensive transfusion reaction occurs when the blood recipient's blood pressure drops suddenly and severely. Blood pressure rebounds once the transfusion is stopped.
- Post-transfusion purpura usually occurs 5–12 days after transfusion, when the recipient of platelets begins to produce antibodies against the donor platelets. This results in destruction of both the donor AND the recipient platelets, leading to a potentially fatal low platelet count.

Adverse reactions to mismatched blood (transfusion reaction) is a major risk of blood transfusion. Transfusion reaction occurs when antibodies in the recipient's blood react to foreign blood cells introduced by the transfusion. The antibodies bind to the foreign cells and destroy them. This destruction is called a hemolytic reaction. In addition, a transfusion reaction may also cause a hypersensitivity of the immune system that may in turn result in tissue damage within the patient's body. The patient may also have an allergic reaction to mismatched blood.

The first symptoms of transfusion reaction are a feeling of general discomfort and **anxiety**. Breathing difficulties, flushing, and a sense of pressure in the chest or back **pain** may also be present. Evidence of a hemolytic reaction can be seen in the urine, which will be colored from the hemoglobin leaking from the destroyed red blood cells. Severe hemolytic reactions are occasionally fatal. Reactions to mismatches of minor factors are milder. These symptoms include itchiness, dizziness, **fever**, **headache**, rash, and swelling. Sometimes the patient will experience breathing difficulties and **muscle spasms**. Most adverse reactions from mismatched blood are not life-threatening.

Infectious diseases can also be transmitted through donated blood and constitute another major risk of blood transfusion. The infectious diseases most often acquired from blood transfusion in the United States are hepatitis and HIV.

Patients who are given too much blood can develop high blood pressure, a concern for people who have heart disease. Very rarely, an air **embolism** is created when air is introduced into a patient's veins through the tubing used for intravenous infusion. The danger of embolism is greatest when infusion is begun or ended. Care must be taken to ensure that all air is bled out of the tubing before infusion begins, and that the infusion is stopped before air can enter the patient's blood system.

Results

Most individuals will feel only a slight sting from the needle used during the blood donation process, and will not experience any side effects after the procedure is over. Plasma is regenerated by the body within 24 hours, and RBCs within a few weeks. Patients who receive a blood transfusion will usually experience mild or no side effects.

Morbidity and mortality rates

The risk of acquiring an **infectious disease** from a blood transfusion is very low. The risk of HIV transmission is 1 in 2,135,000 units of blood; **hepatitis B** virus (HBV), 1 in 205,000 units; and **hepatitis C** virus (HCV), 1 in 1,935,000 units. Bacterial contamination (a cause of infection) is identified in 1 in 500,000 for RBC units and 1 in 15,400 for apheresis platelet units.

KEY TERMS

ABO blood groups—A system in which human blood is classified according to the A and B antigens found in red blood cells. Type A blood has the A antigen, type B has the B antigen, AB has both, and O has neither.

Antibody—A simple protein produced by the body to destroy bacteria, viruses, or other foreign bodies. The production of each antibody is triggered by a specific antigen.

Antigen—A substance that stimulates the immune system to manufacture antibodies (immunoglobulins). The function of antibodies is to fight off such intruder cells as bacteria or viruses. Antigens stimulate the blood to fight other blood cells that have the wrong antigens. If a person with blood type A is given a transfusion with blood type B, the A antigens will fight the foreign blood cells as though they were an infectious agent.

Apheresis—A procedure in which whole blood is withdrawn from a donor, a specific blood component is separated and collected, and the remainder is reinfused into the patient.

Autologous blood—The patient's own blood, drawn and set aside before surgery for use during surgery in case a transfusion is needed.

Fractionation—The process of separating the various components of whole blood.

Hemoglobin—The red pigment in red blood cells that transports oxygen.

Hemolysis—The destruction of red blood cells through disruption of the cell membrane, resulting in the release of hemoglobin. A hemolytic transfusion reaction is one that results in the destruction of red blood cells.

Immunoglobulin—An antibody.

Infusion—Introduction of a substance directly into a vein or tissue by gravity flow.

Injection—Forcing a fluid into the body by means of a needle and syringe.

Plasma—The liquid portion of blood, as distinguished from blood cells. Plasma constitutes about 55% of blood volume.

Platelets—Disk-shaped structures found in blood that play an active role in blood clotting. Platelets are also known as thrombocytes.

Rh (Rhesus) factor—An antigen present in the red blood cells of 85% of humans. A person with Rh factor is Rh positive (Rh+); a person without it is Rh negative (Rh-). The Rh factor was first identified in the blood of a rhesus monkey.

Serum (plural, sera)—The clear fluid that separates from blood when the blood is allowed to clot completely. Blood serum can also be defined as blood plasma from which fibrinogen has been removed.

In about 1 in 600,000 to 800,000 transfusions a fatal misidentification error occurs, and in about 1 in 12,000 to 19,000 cases a non-fatal error occurs.

Alternatives

There are several alternatives to blood transfusion. These include:

- Volume expanders. Certain fluids (saline, Ringer's lactate solution, dextran, etc.) may be used to increase the patient's blood volume without adding additional blood cells.
- Blood substitutes. Much research is currently being done into compounds that can replace some or all of the functions of blood components. One such compound, called HBOC-201 or Hemopure, is hemoglobin derived from bovine (cow) blood. Hemopure shows promise as a substitute for RBC transfusion.
- Bloodless surgery. It may be possible to avoid excessive blood loss through careful planning prior to surgery. Specialized instruments can minimize the amount of blood lost during a procedure. It is also possible to collect some of the blood lost during surgery and reinfuse it into the patient at the end of the operation.

Health care team roles

Blood may be donated at hospital donor centers, Red Cross chapter houses, or other locations where special blood drives have been organized (churches, places of business, schools, colleges, etc.). The procedure of blood donation is generally performed by a nurse or phlebotomist (a person who has been trained to draw blood). Blood transfusions are generally administered in a hospital or emergency center with a blood bank.

Transhepatic biliary catheterization

Definition

Transhepatic biliary catheterization is a surgical procedure during which a catheter is inserted into the bile duct to relieve an obstruction.

Purpose

Bile is a fluid made in the liver and stored in the gall bladder. The function of bile is to break down fats during digestion. When fatty foods move into the intestine, bile is released from the gall bladder, travels through the bile duct, and enters the first part of the small intestine (duodenum).

If the bile duct is blocked, the skin becomes yellowish (jaundiced), the abdomen is painful, and a **fever** develops. The bile duct can be blocked by **gallstones**, surgical injury, infection in the duct, or by tissue growth due to cancer. Transhepatic biliary catheterization is performed to relieve bile duct blockage. The most common reason for this procedure is to relieve obstruction from the overgrowth of cancer cells. Obstruction due to gallstones is usually cleared by other means.

Precautions

Transhepatic biliary catheterization is done when cancer has progressed to the point where all the malignant cells cannot be removed by surgery. Patients who need transhepatic biliary catheterization often have additional complications of their cancer. Because of the likelihood of bleeding from the liver, this procedure should not be done on patients who have blood clotting abnormalities.

Description

Transhepatic biliary catheterization is performed by inserting a needle through the skin, into the abdomen, through the liver, and into the bile duct. A wire attached to the needle then guides the catheter into place. The procedure can take several hours. The patient is given medication for **pain**.

The catheter can either reestablish bile flow into the duodenum or reroute the bile so it drains into a bag outside the body. The choice depends on the extent and position of the obstruction.

Preparation

The standard preoperative blood tests are performed. The patient should not eat or drink the day of the procedure.

Aftercare

The patient must stay in bed after the procedure for at least six hours, to reduce the risk of bleeding. A nurse checks vital signs and looks for indications of complication such as pain, cramping, or leakage

around the catheter. The catheter is flushed periodically to keep it open. Patient and caregiver education on how to keep the catheter clean and irrigated is an important part of aftercare.

Risks

The most common complication of transhepatic biliary catheterization is bleeding as a result of puncturing the liver. Infection may also result from this procedure. Sometimes the catheter itself becomes blocked and is ineffective.

Results

Transhepatic biliary catheterization is a treatment, not a cure. Successful treatment relieves the blocked bile duct, but does not change the underlying conditions that caused the blockage.

Transient ischemic attack

Definition

A transient ischemic attack, or TIA, is often described as a mini-stroke. Unlike a **stroke**, however, the symptoms can disappear within a few minutes. TIAs and strokes are both caused by a disruption of the blood flow to the brain. In TIAs and most strokes, this disruption is caused by a blood clot blocking one of the blood vessels leading to the brain. The blockage produces symptoms such as sudden weakness or numbness on one side of the body, sudden dimming or loss of vision, and difficulty speaking or understanding speech. If the symptoms are caused by a TIA, they last less than 24 hours and do not cause brain damage. Stroke-associated symptoms, on the other hand, do not go away and may cause brain damage or death. TIAs can serve as an early warning sign of stroke and require immediate medical attention.

Demographics

Between 200,000 and 500,000 people in the United States experience a TIA each year. However, this number may be low, since symptoms are transient and not everyone experiencing them will see a doctor. The risk of a TIA increases with age from about 0.1 per 100,000 people under age 50 to 11.7 people per 1,000 over age 80. Of people who have a TIA, roughly one-third will never have another, while the others will go on to have additional TIAs or a stroke. About 15% of people who have a stroke had a previous TIA.

Description

Strokes are the fourth leading cause of death in the United States and the leading cause of disability. Approximately 795,000 Americans have strokes annually; with 137,000 dying. Research shows that 1 in 18 deaths are caused by strokes. About 85% of these strokes are classified as ischemic. In ischemic stroke, a blood vessel leading to the brain becomes blocked and an area of the brain is deprived of oxygenated blood. (The other 15% of strokes are caused by bleeding from a blood vessel that has ruptured.) Without the blood supply, the cells in that area of the brain die. Since brain cells cannot grow back, the functions that are controlled by that brain area may be permanently lost.

Approximately 15% of strokes are preceded by one or more TIAs. However, an estimated one-third of all TIAs are followed by a stroke within five years. In fact, about 5% of people with a TIA will go on to have a stroke within two days of their TIA; 10-15% will have a stroke within three months of their TIA. Transient ischemic attacks are considered a medical emergency and prompt medical attention is very important.

Risk factors for strokes and TIAs are very similar. The risk of a TIA or stroke is higher among men, African Americans, people over age 65, and people with **heart disease** or diabetes. Smokers, people with high blood pressure, and people who are overweight also have a greater risk for TIAs and strokes.

Causes and symptoms

A TIA is caused by a temporary blockage of one of the arteries that leads into the brain. Small **blood clots**, called microemboli, are the immediate cause of the blockage. The blockage forms because of damage or disease within the circulatory system. Blood clots can form in blood vessels because of artery damage, **vascular disease**, and other cardiovascular problems. For example, atherosclerosis is strongly associated with TIAs. Atherosclerosis is the build-up of fatty

deposits or plaque at certain areas in the circulatory system. Clotting cells in blood, called platelets, tend to stick to atherosclerotic plaques or other damaged sites within blood vessels. Occasionally, a clot may grow large enough to block a blood vessel, or a piece of a clot may break off and circulate to other areas of the body. If a clot does not dissolve quickly enough, it can lodge in a blood vessel and block it. In TIAs, the microemboli dissolve within a short time.

Blood flows into the brain through two main pathways: the carotid arteries and the vertebrobasilar arteries. The carotid arteries are located on the front of the neck; the vertebrobasilar arteries are at the base of the skull at the back of the head. The symptoms produced by a TIA are determined by the arteries affected.

If a vertebrobasilar artery is blocked, common symptoms include double vision and **dizziness**, **nausea and vomiting**, difficulty speaking, and problems understanding and using spoken words. There may also be numbness around the mouth and a tingling sensation in the limbs. Blockage of a carotid artery produces complete loss of vision, dimmed or foggy vision, and **paralysis** or weakness on one side of the body. These symptoms also may be accompanied by language problems and speech difficulty. With either type of blockage, the microemboli dissolve within hours and full function returns.

Diagnosis

Examination

The goal of diagnosis is to identify the precise cause of the TIA and to recommend treatment. Initial information that an individual can supply includes a medical history, what drugs are currently being taken

and why, and a full description of the symptoms. Blood tests are ordered to screen blood counts—the numbers of specific blood cell types—and to measure glucose (sugar) and lipid (fats, including **cholesterol**) levels. Based on this information and a **physical examination** that includes blood pressure, pulse, and respiration measurements, one or more of the following imaging tests are ordered.

Tests

A computed tomography scan (CT scan) or a **magnetic resonance imaging** (MRI) scan usually is the first imaging test. CT or MRI can rule out other problems such as a tumor or **subdural hematoma** that can mimic the symptoms of a TIA. A CT scan also can uncover aneurysms and arteriovenous malformation, both of which are blood vessel abnormalities that can cause bleeding in the brain.

Another useful imaging test is carotid ultrasonography, a noninvasive procedure that allows examination of the interior of the carotid artery. This examination can detect carotid stenosis, a condition in which the artery is abnormally narrow because of atherosclerosis. Ultrasonography is very reliable in identifying stenosis, but it does not give enough information to accurately assess the degree of stenosis. Because treatment depends on the degree of stenosis, treatment decisions cannot be based on ultrasonography. Another type of ultrasonography, called **transcranial Doppler ultrasonography**, is used to detect stenosis of the blood vessels within the brain and in the vertebrobasilar arteries.

Procedures

If stenosis is identified, a further test called cerebral arteriography may be done. This test is not done if the individual is in poor health, because it may be too risky. Arteriography involves injecting a special dye into the blood vessels that makes them visible on x rays. This procedure also is used to find suspected problems with blood vessels in the brain. Because it is an invasive procedure, complications can arise. Typically, these complications are minor and temporary. In a very small percentage of people with cardiovascular disease, the procedure may cause serious complications, such as stroke.

Although TIAs affect the brain, the ultimate cause of the problem may be found in the heart. Heart disease or damage to the heart's blood vessels is assessed by **echocardiography**. Echocardiography is a type of ultrasonography and is a noninvasive procedure.

Treatment

Treatment is aimed at preventing further TIAs and especially at preventing a stroke. The particular therapy depends on the root cause of the TIA and is not begun until this cause is identified. If possible, drug therapy is the preferred method of treating TIAs. Surgical intervention may be required if an individual's situation is not likely to respond to medication or if medication has failed.

Drugs

Anticlotting drugs such as **aspirin** or cloplidgrel (Plavix) usually are given to reduce the chance of platelets forming clumps in the blood. These drugs are intended for long-term use. Anticoagulant (blood thinner) drugs such as warfarin (Coumadin) may be prescribed to keep blood from clotting. Other drugs may be prescribed to relax the smooth muscles of the arteries. Cholesterol-lowering drugs (statins) may be recommended, and conditions such as high blood pressure (**hypertension**) and **diabetes mellitus** that can worsen vascular disease will be treated.

Surgery

If carotid arteriography reveals at least a 70% blockage of the carotid artery, surgical treatment usually is recommended. The particular surgical method is called carotid **endarterectomy**. In endarterectomy, the artery is opened and the material clogging it is removed. Another procedure, called balloon **angioplasty**, has been suggested for treating carotid stenosis, but it is not as widely used. This procedure is performed by threading a thin tube through the blood vessel to the site that is clogged. A balloon or a stent (a slender rod) is then passed through the tube to mechanically widen the narrowed area. This procedure is successfully used in other blood vessels in the body, but there is some concern that using it close to the brain may be too dangerous. Surgical treatment of blockage of the vertebrobasilar arteries is not usually recommended.

Home remedies and lifestyle changes

Treatment of TIAs also focuses on underlying problems. High blood pressure, heart disease, and high levels of blood lipids all require medical intervention. Condition-specific medications often are prescribed and lifestyle changes are strongly encouraged. These may include:

- losing weight if necessary and maintaining a healthy weight
- stopping smoking

KEY TERMS

Angioplasty—A medical procedure in which a catheter, or thin tube, is threaded through blood vessels. The catheter is used to place a balloon or stent (a small metal rod) at an area of stenosis and expand it mechanically.

Arteriography—A medical test in which an x-ray visible dye is injected into blood vessels. This dye allows the blood vessels to be imaged with x rays.

Atherosclerosis—A build-up of fatty tissue called plaque inside arteries that can impede or block blood flow.

Carotid artery—One of the major blood vessels leading to the brain; it runs up the front of the neck.

Echocardiography—A type of ultrasonography that is used to create an image of the heart and its functioning.

Endarterectomy—A surgical procedure in which diseased tissue and atherosclerotic plaque are removed from the inside of an artery.

Ischemia—A condition in which blood flow is cut off or restricted from a particular area. The surrounding tissue, starved of oxygen and nutrients, dies.

Microemboli—Small blood clots in the bloodstream.

Platelets—Tiny cells in the blood that help form blood clots.

Stenosis—The narrowing of an opening or passageway in the body. In arteries, stenosis is caused by a build-up of atherosclerotic plaque, disease, or other disorder.

Stroke—A condition in which blood flow to the brain has been blocked, thereby causing brain cells to die from lack of oxygen and nutrients; also called a "brain attack."

Ultrasonography—A medical test in which sound waves are directed against internal structures in the body. As sound waves bounce off the internal structure, they create an image on a video screen.

Vertebrobasilar arteries—Major blood vessels that lead to the brain. They are located at the base of the skull at the back of the head.

- avoiding alcohol or consuming alcohol in moderation
- exercising moderately but regularly (5 days a week)
- eating a diet low in animal fats and sweets and high in fresh fruits, vegetables, and fiber
- controlling high blood pressure through salt (sodium) restriction, exercise, and medications as necessary
- controlling diabetes through exercise, diet, and medication as necessary by monitoring blood glucose levels regularly

Prognosis

One-third of TIAs are followed by stroke in the next five years; in the other two-thirds, the TIAs may either continue or disappear on their own. However, because of the risk of stroke-related disability and death, all TIAs should be treated as emergency medical situations.

Medical treatment significantly decreases the risk of stroke for people who experience one or more TIAs. Anti-platelet therapy reduces risk as much as 31%. Carotid endarterectomy also substantially reduces stroke risk. The procedure itself carries some risk, but the complication rate is less than 5%. The risk of complication can be lowered by choosing to have the procedure done in a facility experienced with it and by a surgeon with a low complication rate.

Prevention

Treatment for TIAs is complemented by lifestyle changes. These practices also may prevent TIAs and strokes from ever occurring. Doctors and other healthcare providers universally recommend that individuals stop **smoking** and consume alcohol in moderation. Regular health checkups can detect high blood pressure, heart disease, and other underlying problems. Adhering to treatment for these problems can help minimize TIA and stroke risks. Finally, maintaining a healthy weight and engaging in regular **exercise** as able are strongly recommended.

Translational medicine

Definition

Translational medicine is the process of turning findings or observations from research into ways to improve health for individuals and the public.

Description

Often called "from bench to bedside," translational medicine involves taking the information learned in clinical trials and the laboratory and applying that information to create drugs or other treatments for diseases and disorders.

In April 2003, scientists completed mapping of the human genome. A genome is the complete set of DNA, which contains all of the genetic instructions for an organism to function. Sequencing the human genome involved billions of calculations. This feat opened the door for expanded research into how mutations or variations on genes cause diseases such as cancer or inherited diseases. For example, though research in cancer treatment traditionally has been based on the tumor's location in the body, new understanding of how genes and molecules act means that cancer research can focuses on specific characteristics of cells that trigger cancer cell growth or fail to stop it. Doing so enables doctors to identify and target these causes of cancer at very precise molecular levels to destroy only the cells involved in the cancer and spare normal, healthy cells.

Identifying genetic causes of diseases is one of the many advanced types of medical research that takes place in public and private laboratories and research centers around the world. Examples of translational medicine in practice include the following:

- Many people who have the eye disease glaucoma have had to place eye drops in their eyes several times a day to manage the disease and prevent blindness. Erin Lavik from Yale University developed microspheres with the glaucoma drug timolol maleate inside that doctors could inject into a patient's eye and that would release the drug regularly.
- A team of researchers at Virginia Commonwealth University developed the compound 5-HMF (relabeled Aes-103) to treat sickle cell disease, a blood disease that affects at least 13 million people around the world.
- James Olson of the Fred Hutchinson Cancer Research Center led a group that discovered how the component in scorpion venom called chlorotoxin can light up brain cancer cells when mixed with a fluorescent dye. Doctors can use it with magnetic resonance imagine (MRI) to help spot the cancerous cells during types of brain surgery.

As of 2014, traditional drug development and approval occurred through pharmaceutical companies and the U.S. Food and Drug Administration (FDA). Before a pharmaceutical company can market a prescription drug in the United States, the company must prove the safety and effectiveness of the drug for specific uses through a series of forms, submissions, and research results. The FDA also oversees safety of medical and radiological devices, food, cosmetics, biologic therapies, and veterinary drugs. The research includes clinical trials that occur in phases, often beginning with animal subjects. Before clinical trials advance to allowing human subjects, a certain degree of safety and effectiveness must be proven, and special rules apply to ensure safe and ethical handling of the trial.

Purpose

Thorough research for pharmaceutical products, medical devices, and other therapies can take years. Even after approval of a drug or therapy, the discoverer must bring the product to market with safe packaging and delivery. According to the National Center

WWW.BOOKBAZ.IR

for Advancing Translational Sciences (NCATS), it can take up to 14 years and $14 billion to develop a new drug or other invention. New discoveries about human genetics are paving the way for more, and more effective, treatments that doctors and patients want to be able to use as soon as possible.

Efforts of the NCATS and many proponents of translational medicine aim to speed the process of developing and making available new drugs and treatments so that as many patients as possible can benefit from them. The NCATS supports approaches that can be shared across sciences and diseases to help remove barriers and bottlenecks in scientific discovery and medical product development. Examples of efforts to improve translational medicine include the following:

- Development of silicon computer chips lined with living cells to mimic human organs. An example is a bioengineered 3-D chip to mimic the breathing motion of a lung for testing of drugs that is more realistic than animal testing.
- A cooperative project with the Michael J. Fox Foundation for Parkinson's Research to use innovative chemical screening methods to identify a chemical compound involved in Parkinson's disease.
- Funding for collaboration of scientists at 22 consortia with representatives of 98 patient advocacy groups to research treatments for patients with rare diseases. By collaborating, the scientists may be able to find common elements across many of the rare diseases.

Preparation

Patients who undergo treatment for complex diseases such as cancer should gather as much information as possible about novel treatments being tested at major academic and research hospitals that specialize in their disease. These facilities likely offer clinical trials and the most advanced diagnosis and treatments in their specialties. Patients should learn about eligibility criteria for participating in the trial and realize that participation is voluntary.

Aftercare

Patients enrolled in medical research such as clinical trials are monitored carefully for safety and complications. Not all treatments tested in trials or just released from research work for every patient. One of the challenges facing translational medicine is how to effectively take results from academic or private research and use the information to improve the health of underserved populations.

KEY TERMS

Genetics—The study of genes and biological inheritance.

Genome—All of the genetic instructions in a cell.

Molecular—Composed of molecules, or studied and addressed at individual and detailed levels. In medicine, this means understanding how genes, proteins, and other molecules on cells cause or affect disease.

Results

Eventually, translational medicine could result in a sort of personalized medicine that targets specific molecular qualities of each individual. To some extent, this already is taking place in cancer treatment, where doctors can target the drivers of cancer cell growth and base a patient's prognosis, or outlook, on specific genetic subtypes of cancer. As collaboration improves in research and more doctors are directly involved in developing therapies and bringing them to market, the speed with which patients can benefit from new discoveries will greatly improve. Even clinical trials may be focused to recruit participants who meet criteria based on specific molecular characteristics of disease.

Risks

Speeding the transition from laboratory or trial to patients' bedsides could increase the potential for introducing medications before all safety risks are identified, especially long-term risks or effectiveness. All translation medicine research should be based on solid evidence. Even with an emphasis on translational medicine and speeding up drug development, many areas of the country, world, or fields of medicine lack qualified investigators to perform research. Each country in which research is conducted, including the United States, must support an environment of public and private sector collaboration for translational medicine to work. Finally, clinical trials must have enough participants enrolled for the results to be valid, which means trials must be well designed and patients must be willing to volunteer for them.

Transplant surgery

Definition

Transplant surgery is the surgical removal of organs, tissue, or blood products from a donor and surgically placing or infusing them into a recipient. There are four categories of transplantation, classified by tissue origin: autograft (donor and recipient are the same person); isograft or syngeneic graft (donor and recipient are genetically identical, as in identical twins); allograft or homograft (donor and recipient are genetically unrelated but belong to the same species, i.e., both are human beings) and xenograft or heterograft (donor and recipient belong to different species, i.e., chimpanzee or rabbit tissues used in humans on an experimental basis).

Description

Organ donors

Organ donors are classified as living donors or cadaveric (nonliving) donors. All donors are carefully screened to make sure there is a suitable blood type match and to prevent any transmissible diseases or other complications.

LIVING DONORS. Living donors may be family members or biologically unrelated to the recipient. Between the 1990s and 2014, the number of biologically unrelated living donors increased tenfold. Living donors must be physically fit, in good general health, and have no existing disorders such as diabetes, high blood pressure, cancer, **kidney disease**, or **heart disease**. Of all the organs transplanted in 2013, about 42% came from living donors. Organs that can be donated from living donors include:

- Single kidneys. In 2013, about 43% of all kidney transplants came from living donors. There is little risk in living with one kidney because the remaining kidney compensates for and performs the work of both.
- Liver. Living donors can donate segments of the liver because the organ can regenerate and regain full function.
- Lung. Living donors can donate lobes of the lung although lung tissue does not regenerate.
- Pancreas. Living donors can donate a portion of the pancreas even though the gland does not regenerate.
- Intestines. Living donors can donate a portion of their intestine.

Organs donated from living donors eliminate the need to place the recipient on the national waiting list. Transplant surgery can be scheduled at a mutually acceptable time rather than performed under emergency conditions. In addition, the recipient can begin taking immunosuppressant medications two days before the transplant surgery to reduce the risk of rejection. Living donor transplants are often more successful than cadaveric donor transplants because there is a better tissue match between the donor and recipient. The living donor's medical expenses are usually covered by the organ recipient's insurance company, but the amount of coverage may vary.

CADAVERIC OR DECEASED DONORS. Organs from cadaveric donors come from people who have recently died and before death willed their organs by signing an organ donor card or from people who are brain-dead. The donor's family must give permission for **organ donation** at the time of death or diagnosis of brain death. Cadaveric donors may be young adults with traumatic head injuries or older adults who had a **stroke**. The majority of deceased donors are older than the general population.

Transplant procedures

ORGAN HARVESTING. Harvesting refers to the process of removing cells or tissues from the donor and preserving them until they are transplanted. If the

WWW.BOOKBAZ.IR

donor is deceased, the organ or tissues are harvested in a sterile operating room. They are packed carefully for transportation and delivered to the recipient via ambulance, helicopter, or airplane. Organs from deceased donors should be transplanted within a few hours of harvesting. After recipients are notified that an organ has become available, they should not eat or drink anything.

When the organ is harvested from a living donor, the recipient's transplant surgery follows immediately after the donor's surgery. The recipient and the donor should not eat or drink anything after midnight the evening before the scheduled operation.

PREOPERATIVE PROCEDURES. After arriving at the hospital, recipients have a complete physical and such other tests as a chest x ray, blood tests, and an electrocardiogram (EKG) to evaluate their fitness for surgery. If the recipient has an infection or major medical problem, or if the donor organ is found to be unacceptable, the operation is canceled.

The recipient is prepared for surgery by having the incision site shaved and cleansed. An intravenous tube (IV) is placed in the arm to deliver medications and fluids, and a sedative is given to help the patient relax.

TRANSPLANT SURGERY. After the patient has been brought to the operating room, the anesthesiologist administers a general anesthetic. A central venous catheter may be placed in a vein in the patient's arm or groin. A breathing tube is placed in the patient's throat. The breathing tube is attached to a mechanical ventilator that expands the lungs during surgery.

The patient is then connected to a heart-lung bypass machine, also called a cardiopulmonary bypass pump, which takes over for the heart and lungs during the surgery. The heart-lung machine removes carbon dioxide from the blood and replaces it with oxygen. A tube is inserted into the patient's aorta to carry the oxygenated blood from the bypass machine back to the heart for circulation to the body. A **nasogastric tube** is placed to drain stomach secretions, and a urinary catheter is inserted to drain urine during the surgery.

The surgeon carefully removes the diseased organ and replaces it with the donor organ. The blood vessels of the donated organ are connected to the patient's blood vessels, allowing blood to flow through the new organ.

Demographics

The former typical cut-off age for a transplant recipient ranged between 40 and 55 years; however, people aged 50–65 constitute the fastest-growing age group added to the transplant waiting list. A person's general health is usually a more important factor than age. Expanded-criteria kidney donations are responsible for many of these later-life transplants. Kidneys in this category have been donated by people who in the past would not have been considered optimum donors due to age or certain medical conditions. Studies have shown that older persons with kidney failure fare better with an expanded-criteria kidney transplant than by remaining on dialysis. According to the Organ Procurement and Transplant Network, an organization that tracks all transplants done in the United States, there were 28,954 transplants done in the United States in 2013.

The national waiting list for most transplanted organs continues to grow every year. As of June 2014, there were about 123,000 eligible recipients waiting for an organ transplant in the United States. Of these, about 101,000 were waiting for kidneys, about 16,000 were waiting for livers, and about 4,000 were waiting for hearts.

Purpose

Transplant surgery is a treatment option for diseases or conditions that have not improved with other medical treatments and have led to organ failure or injury. Transplant surgery is generally reserved for people with end-stage disease who have no other options.

The decision to perform transplant surgery is based on the patient's age, general physical condition, specific diagnosis, and stage of the disease. Transplant surgery is not recommended for patients who have liver, lung, or kidney problems; poor leg circulation; cancer; or chronic infections.

Preparation

Pre-transplant evaluation

Several tests are performed before the transplant surgery to make sure that the patient is eligible to receive the organ and to identify and treat any problems ahead of time. Common pre-transplant tests include:

- tissue typing
- blood tests
- chest x ray
- pulmonary function tests
- computed tomography (CT) scan
- heart function tests (electrocardiogram, echocardiogram, and cardiac catheterization)
- sigmoidoscopy
- bone densitometry test

The pre-transplant evaluation usually includes a dietary and social work assessment. In addition, the patient must undergo a complete dental examination to reduce the risk of infection from bacteria in the mouth.

Insurance considerations

Organ transplantation is an expensive procedure. Insurance companies and health maintenance organizations (HMOs) may not cover all costs. Many insurance companies require precertification letters of medical necessity. As soon as transplantation is discussed as a treatment option, patients should contact their insurance provider to determine what costs will be covered. In the United States, a kidney transplant costs over $250,000, a liver transplant over $550,000, and a heart transplant almost $1,000,000. There are, however, organizations that can assist with raising funds to cover the cost of transplantation, such as the National Foundation for Transplants and the National Transplant Assistance Fund and Catastrophic Injury Program.

Patient education and lifestyle changes

Before undergoing transplant surgery, the transplant team ensures that the patient understands the potential benefits and risks of the procedure. In addition, a team of healthcare providers review the patient's social history and psychological test results to ensure that the patient is able to comply with the regimen that is needed after transplant surgery. An organ transplant requires major lifestyle changes, including dietary adjustments, complex drug treatments, and frequent examinations. The patient must be committed to making these changes in order to become a candidate for transplant. Most transplant centers have extensive patient education programs.

Smoking cessation is an important consideration for patients who use tobacco. Many transplant programs require the patient to be a nonsmoker for a certain amount of time (usually six months) before being eligible to participate in the pre-transplant screening evaluation. The patient must also be committed to avoid tobacco products after the transplant.

Informed consent

Patients are legally required to sign an informed consent form prior to transplant surgery. Informed consent signifies that the patient is a knowledgeable participant in making healthcare decisions. The doctor discusses all of the following with the patient before the patient signs the form: the nature of the surgery; reasonable alternatives to the surgery; and the risks, benefits, and uncertainties of each option. Informed consent also requires the doctor to make sure that the patient understands the information that has been given.

Finding a donor

After the patient has completed the pre-transplant evaluation and has been approved for transplant surgery, the next step is locating a donor. Organs from cadaveric donors are located through a computerized national waiting list maintained by the United Network for Organ Sharing (UNOS) to assure equal access to and fair distribution of organs. When a deceased organ donor is identified, a transplant coordinator from an organ procurement organization enters the donor's data in the UNOS computer. The computer then generates a list of potential recipients. This list is called a match run. Factors affecting a potential organ recipient's ranking on the match run list include: tissue match, blood type, size of the organ, length of time on the waiting list, immune status, and the geographical distance between the recipient and donor. For some transplants, such as heart, liver, and intestinal segments, the degree of medical urgency is also taken into consideration.

The organ is offered to the transplant team of the first person on the ranked waiting list. The recipient must be healthy enough to undergo surgery, available, and willing to receive the organ transplant immediately. The matching process involves cross matching and performing an antibody screen and a host of other tests.

Donor searching can be a long and stressful process. A supportive network of friends and family is important to help the patient cope during this time. The healthcare provider or social worker can also put the patient in touch with support groups for transplant patients.

Contact and travel arrangements

The patient must be ready to go to the hospital as soon as possible after being notified that an organ is available. A suitcase should be kept packed at all times. Transportation arrangements should be made ahead of time. If the recipient lives more than a 90-minute drive from the transplant center, the transplant coordinator helps to make transportation arrangements for the recipient and one friend or family member.

Because harvested organs cannot be preserved for more than a few hours, the transplant team must be able to contact the patient at all times. Some transplant programs offer a pager rental service or cell phone to be used only for receiving the call from the transplant

WWW.BOOKBAZ.IR

center. The patient should clear travel plans with the transplant coordinator before taking any trips.

Blood donation and conservation

Some transplant centers allow patients to donate their own blood before surgery, which is known as autologous donation. Autologous blood is the safest blood for **transfusion**, since there is no risk of disease transmission. Preoperative donation is an option for patients receiving an organ from a living donor, since the surgery can be scheduled in advance. In autologous donation, the patient donates blood once a week for one to three weeks before surgery. The blood is separated and the blood components needed are re-infused during the operation.

In addition to preoperative donation, there are several techniques for minimizing the patient's blood loss during surgery:

- Intraoperative blood collection. The blood lost during surgery is processed, and the red blood cells are re-infused during or immediately after surgery.
- Immediate preoperative hemodilution. The patient donates blood immediately before surgery to decrease the loss of red blood cells during the operation. The patient is then given fluids to restore the volume of the blood.
- Postoperative blood collection. The blood lost from the incision following surgery is collected and re-infused after the surgical site has been closed.

Aftercare

Inpatient recovery

A transplant recipient can expect to spend three to four weeks in the hospital after surgery. Immediately following the operation, the patient is transferred to an intensive care unit (ICU) for close monitoring of the patient's vital signs. When the patient's condition is stable, the person is transferred to a hospital room, usually in a specialized transplant unit. The IV in the patient's arm, the urinary catheter, and a dressing over the incision remain in place for several days. A chest tube may be placed to drain excess fluids. Special stockings may be placed on the patient's legs to prevent **blood clots** in the deep veins of the legs. A breathing aid called an incentive spirometer is used to help keep the patient's lungs clear and active after surgery.

Medication to relieve **pain** is given every three to four hours or through a device known as a PCA (patient-controlled **anesthesia**). The PCA is a small pump that delivers a dose of medication into the IV when the patient pushes a button. The transplant recipient is also given immunosuppressive medications to reduce the risk of organ rejection. These medications are typically taken by the recipient for the rest of the person's life.

A 2–4 week waiting period is necessary before the transplant team can evaluate the success of the procedure. Visitors are limited during this time to minimize the risk of infection. The patient is given intravenous antibiotic, antiviral, and antifungal medications, as well as blood and platelet transfusions to help fight off infection and prevent excessive bleeding. Blood tests are performed daily to monitor the patient's kidney and liver function, as well as his or her nutritional status. Other tests are performed as needed.

Outpatient recovery

After leaving the hospital, the transplant recipient is monitored through home or outpatient visits for as long as a year. Medication adjustments are often necessary, but barring complications, the recipient can return to normal activities about 6–8 months after the transplant.

Proper outpatient care includes:

- taking medications exactly as prescribed
- attending all scheduled follow-up visits

Results

In a successful organ transplant, the patient returns to a more nearly normal lifestyle with increased strength and stamina.

Morbidity and mortality rates

Mortality figures for transplant surgery include recipients who die before a match with a suitable donor can be found. About 18 patients die every day in the United States waiting for a transplant.

The Organ Procurement and Transplantation Network gives the first-year survival rates for transplant surgery as follows:

- 94% of pancreas transplant recipients
- 96% of kidney transplant recipients
- 88% of liver transplant patients

- 88% of heart transplant patients
- 84% of lung transplant patients

Three-year survival rates are:

- 91% for kidney transplant patients
- 90% for kidney/pancreas transplant patients
- 80% for liver transplant patients
- 79% for heart transplant patients
- 63% for lung transplant patients

Alternatives

Clinical trials

Available alternatives to transplant surgery depend upon the individual patient's diagnosis and severity of illness. Some patients may be eligible to participate in clinical trials, which are research programs that evaluate a new medical treatment, drug or device.

Experimental surgeries

Some surgeons are working to expand the type of transplants that are available to patients. In some cases, these surgeons find a single individual with very specific characteristics that is a good candidate for a new type of surgery. Generally, these patients are otherwise very healthy and have no other viable options. These new surgeries are done very infrequently, often with a staff of more than 100, and are considered very risky. Over time as more is learned about how patients react and surgical techniques are improved, the new surgery may be made available to more patients.

In 2005 a surgical team in France completed the first partial face transplant on a living human. After that, a handful of other surgical teams have undertaken face transplants, with a Spanish surgical team completing the first full face transplant in 2010.

Complementary and alternative (CAM) therapies

Complementary therapies can be used along with standard treatments to help alleviate the patient's pain; strengthen muscles; and decrease depression, **anxiety**, and **stress**. Before trying a complementary treatment, however, patients should check with their doctors to make sure that it will not interfere with standard therapy or cause harm. Alternative approaches that have helped transplant recipients maintain a positive mental attitude both before and after surgery include **meditation**, **biofeedback**, and various relaxation techniques. **Massage therapy**, **music therapy**, **aromatherapy**, and **hydrotherapy** are other types of treatment that can offer patients some pleasant sensory experiences as well as relieve pain. **Acupuncture** has been shown in a number of NIH-sponsored studies to be effective in relieving nausea and **headache**, as well as chronic muscle and joint pain. Some insurance carriers cover the cost of acupuncture treatments.

KEY TERMS

Antibody—A substance produced by the immune system in response to specific antigens, thereby helping the body fight infection and foreign substances. An antibody screen involves mixing the white blood cells of the donor with the serum of the recipient to determine if antibodies in the recipient react with the antigens of the donor.

Autologous blood—The patient's own blood, drawn and set aside for use during surgery in case a transfusion is needed.

Bone densitometry test—A test that quickly and accurately measures the density of bone.

Brain death—Irreversible cessation of brain function. Patients with brain death have no potential capacity for survival or for recovery of any brain function.

Cadaveric donor—An organ donor who has recently died of causes not affecting the organ intended for transplant.

Donor—A person who supplies organ(s), tissue, or blood to another person for transplantation.

Harvesting—The process of removing tissues or organs from a donor and preserving them for transplantation.

Hemodilution—A technique in which the fluid content of the blood is increased without increasing the number of red blood cells.

Organ procurement—The process of donor screening and the evaluation, removal, preservation, and distribution of organs for transplantation.

Pulmonary function test—A test that measures the capacity and function of the lungs as well as the blood's ability to carry oxygen. During the test, the patient breathes into a device called a spirometer.

Rejection—An immune response that occurs when a transplanted organ is viewed as a foreign substance by the body. If left untreated, rejection can lead to organ failure and even death.

WWW.BOOKBAZ.IR

Risks

Short-term risks following an organ transplant include **pneumonia** and other infectious diseases; excessive bleeding; and liver disorders caused by blocked blood vessels. In addition, the new organ may be rejected, which means that the patient's immune system is attacking the new organ. Characteristic signs of rejection include **fever**, rash, **diarrhea**, liver problems, and a compromised immune system. Transplant recipients are given immunosuppressive medications to minimize the risk of rejection. In most cases, the patient will take these medications for the rest of his or her life.

Long-term risks include an elevated risk of cancer, particularly **skin cancer**. An estimated 6–8% of transplant patients develop cancer over their lifetime as compared to less than 1% in the general population.

There is a very small risk of infection from a transplanted organ, even though donors in the United States and Canada are carefully screened. In 2007, the Centers for Disease Control and Prevention (CDC) reported a case in which four organ recipients in the Chicago area developed **hepatitis C** and HIV infection from a high-risk donor. The diseases did not show up on screening tests because the donor contracted them about three weeks before his death, when there were not enough antibodies in his blood to be detected by present tests.

Transposition of the great arteries

Definition

Transposition of the great arteries is a birth defect causing a fatal condition in which there is a reversal, or switch, in the truncal connections of the two main

(great) blood vessels to the heart, the aorta and pulmonary artery.

Demographics

In the United States, transposition of the great artery is one of the most common congenital heart defects It is more common in males than in females, race is not a factor, and it affects about 40 out of every 100,000 babies born. The mortality rate in untreated patients is approximately 30% in the first week, 50% in the first month, and 90% by the end of the first year. With improved diagnostic, medical, and surgical techniques, the overall short-term and midterm survival rate exceeds 90%.

Description

There are two great arteries, the pulmonary artery and the aorta. Normally, the pulmonary artery carries blood from the right ventricle to the lungs. The aorta carries blood from the left ventricle to the vessels of the rest of the body.

Normally, blood returning to the heart is depleted in oxygen. It goes first to the right atrium of the heart and then to the right ventricle where it is pumped to the lungs. While in the lungs, the blood picks up more oxygen. After the lungs, the blood flows to the left atrium, then the left ventricle, which pumps the blood out through the aorta to the rest of the body, thereby supplying the body with oxygenated blood.

Transposition of the great arteries results in oxygen-depleted blood going to the body. The reason is that the connection of the two great arteries is reversed. In this case, the aorta is connected to the right ventricle. Blood returning to the heart goes to the right atrium and ventricle, which is normal. Then, when the right ventricle pumps the blood out, it goes into the aorta for distribution throughout the body. At the same time, blood in the lungs goes to the left atrium, the left ventricle, but then back to the lungs. This happens because the pulmonary artery is connected to the left ventricle. The result is that highly-oxygenated blood keeps recycling through the lungs, while oxygen-depleted blood recycles through the body without going through the lungs to reoxygenate.

This condition develops during the fetal stage and must be treated promptly after birth if the newborn is to survive. The newborn can survive for a few days because the foramen ovale, a small hole in the septum that separates the two atria, is open, allowing some oxygenated blood to escape and mix into the blood that is being pumped throughout the body. However, the foramen ovale normally closes within a few days after birth.

KEY TERMS

Aorta—The biggest artery in the body, receiving blood directly from the heart.

Artery—A blood vessel that carries blood away from the heart to the rest of the body.

Atrium—One of the two upper chambers of the heart.

Blood vessels—General term for arteries, veins, and capillaries that transport blood throughout the body.

Pulmonary artery—The blood vessel that delivers blood from the heart to the lungs.

Ventricle—A cavity, as in the brain or heart. The right ventricle of the heart drives blood from the heart into the pulmonary artery, which supplies blood to the lung.

Causes and symptoms

Transposition of the great arteries is a birth defect that occurs during fetal development. There is no identifiable disease or cause. The main symptom is blueness of the skin caused by a general lack of oxygen in the body's tissues. Other symptoms include, **shortness of breath**, poor feeding, and chubbing of the fingers or toes.

Diagnosis

Diagnosis is made immediately after birth, when it is observed that the newborn is lacking oxygen. This is noted by the bluish color of the newborn, indicating **cyanosis**, a lack of oxygen. A definite diagnosis is made by x ray, **electrocardiography** (ECG), and **echocardiography**.

Treatment

The only treatment for this condition is prompt heart surgery shortly after birth. In surgery, the two great arteries are reconnected to their proper destination. This restores the normal blood flow pattern. The coronary arteries are also reconnected, so that they can supply blood to the heart itself. During the procedure at birth, the baby will receive prostaglandin through an IV (intravenous line). This medication helps the blood flow through the lungs and body. A procedure using

WWW.BOOKBAZ.IR

cardiac catheterization may also be needed to create a large hole in the atrial septum to allow blood to mix. In many hospitals, a type of surgery called an arterial switch procedure can be used to permanently correct the problem within the first week of life. This surgery switches the great arteries back to the normal position along with the coronary arteries.

Prognosis

Improvement in symptoms, along with growth and development is seen after surgical correction of the defect. However, left untreated, this disease can be fatal within the first weeks of life.

Prevention

Because there is no identifiable cause, there is no way to prevent this condition. Women who plan to become pregnant should be immunized against **rubella** if they are not already immune. Avoiding alcohol, eating healthy, and controlling diabetes both before and during **pregnancy** may also be helpful.

Transurethral bladder resection

Definition

Transurethral bladder resection is a surgical procedure used to view the inside of the bladder, remove tissue samples, and/or remove tumors. Instruments are passed through a cystoscope (a slender tube with a lens and a light) that has been inserted through the urethra into the bladder.

Purpose

Transurethral resection is the initial form of treatment for bladder cancers. The procedure is performed to remove and examine bladder tissue and/or a tumor. It may also serve to remove lesions, and it may be the only treatment necessary for noninvasive tumors. This procedure plays both a diagnostic and therapeutic role in the treatment of bladder cancers.

Demographics

According to the American Cancer Society (ACS), there were 72,570 new cases of **bladder cancer** in the United States in 2013, with approximately 15,210 deaths from the disease.

Industrialized countries such as the United States, Canada, France, Denmark, Italy, and Spain have the highest incidence rates for bladder cancer. Rates are lower in England, Scotland, and Eastern Europe. The lowest rates occur in Asia and South America.

Smoking is a major risk factor for bladder cancer; it increases a person's cancer risk by two to five times and accounts for approximately 50% of bladder cancers found in men and 30% found in women. If cigarette smokers quit, their risk declines in two to four years. Exposure to a variety of industrial chemicals also increases the risk of developing this disease. Occupational exposures may account for approximately 25% of all urinary bladder cancers.

Men have a 1-in-30 chance of developing bladder cancer; women have a 1-in-90 chance of developing bladder cancer. The incidence of bladder cancer in the Caucasian population is almost twice that of the African American population. For other ethnic and racial groups in the United States, the incidence of bladder cancer falls between that of Caucasians and African Americans.

There is a greater incidence of bladder cancer with advancing age. Of newly diagnosed cases in both men and women, approximately 80% occur in people aged 60 years and older.

Description

Cancer begins in the lining layer of the bladder and grows into the bladder wall. Transitional cells line the inside of the bladder. Cancer can begin in these lining cells.

During transurethral bladder resection, a cystoscope is inserted through the urethra into the bladder. A clear solution is infused to maintain visibility and the tumor or tissue to be examined is cut away using an electric current. A biopsy is taken of the tumor and muscle fibers in order to evaluate the depth of tissue involvement, while avoiding perforation of the bladder wall. Every attempt is made to remove all visible

KEY TERMS

Biopsy—The removal and microscopic examination of a small sample of body tissue to see whether cancer cells are present.

Bladder irrigation—Flushing or rinsing the bladder with a stream of liquid (as in removing a foreign body or medicating).

Bladder tumor marker studies—A test to detect specific substances released by bladder cancer cells into the urine using chemicals or immunology (using antibodies).

Bladder washing—A procedure in which bladder washing samples are taken by placing a salt solution into the bladder through a catheter (tube) and then removing the solution for microscopic testing.

Chemotherapy—The treatment of cancer with anticancer drugs.

Cystoscopy—A procedure in which a slender tube with a lens and a light is placed into the bladder to view the inside of the bladder and remove tissue samples.

Immunotherapy—A method of treating allergies in which small doses of substances that a person is allergic to are injected under the skin.

Interstitial radiation therapy—The process of placing radioactive sources directly into the tumor. These radioactive sources can be temporary (removed after the proper dose is reached) or permanent.

Intravenous pyelogram—An x ray of the urinary system taken after injecting a contrast solution that enables the doctor to see images of the kidneys, ureters, and bladder.

Metastatic—A change of position, state, or form; as a transfer of a disease-producing agency from the site of disease to another part of the body; a secondary growth of a cancerous tumor.

Noninvasive tumors—Tumors that have not penetrated the muscle wall and/or spread to other parts of the body.

Radiation therapy—The use of high-dose x rays to destroy cancer cells.

Retrograde pyelography—A test in which dye is injected through a catheter placed with a cystoscope into the ureter to make the lining of the bladder, ureters, and kidneys easier to see on x rays.

Ureters—Two thin tubes that carry urine downward from the kidneys to the bladder.

Urethra—The small tube-like structure that allows urine to empty from the bladder.

Urine culture—A test to check for the presence of bacteria in urine.

Urine cytology—The examination of the urine under a microscope to look for cancerous or precancerous cells.

tumor tissue, along with a small border of healthy tissue. The resected tissue is examined under the microscope for diagnostic purposes. An indwelling catheter may be inserted to ensure adequate drainage of the bladder postoperatively. At this time, interstitial **radiation therapy** may be initiated, if necessary.

Diagnosis

If there is reason to suspect a patient may have bladder cancer, the physician will use one or more methods to determine if the disease is actually present. The doctor first takes a complete medical history to check for risk factors and symptoms, and does a **physical examination**. An examination of the rectum and vagina (in women) may also be performed to determine the size of a bladder tumor and to see if and how far it has spread. If bladder cancer is suspected, the following tests may be performed, including:

- biopsy
- cystoscopy
- urine cytology
- bladder washing
- urine culture
- intravenous pyelogram
- retrograde pyelography
- bladder tumor marker studies

Most of the time, the cancer begins as a superficial tumor in the bladder. Blood in the urine is the usual warning sign. Based on how they look under the microscope, bladder cancers are graded using Roman numerals 0 through IV. In general, the lower the number, the less the cancer has spread. A higher number indicates greater severity of cancer.

Because it is not unusual for people with one bladder tumor to develop additional cancers in other areas of the bladder or elsewhere in the urinary system, the doctor may biopsy several different areas of the bladder lining. If the cancer is suspected to have

WWW.BOOKBAZ.IR

spread to other organs in the body, further tests will be performed.

Because different types of bladder cancer respond differently to treatment, the treatment for one patient could be different from that of another person with bladder cancer. Doctors determine how deeply the cancer has spread into the layers of the bladder in order to decide on the best treatment.

Aftercare

As with any surgical procedure, blood pressure and pulse will be monitored. Urine is expected to be blood-tinged in the early postoperative period. Continuous bladder irrigation (rinsing) may be used for approximately 24 hours after surgery. Most operative sites should be completely healed in three months. The patient is followed closely for possible recurrence with visual examination, using a special viewing device (cystoscope) at regular intervals. Because bladder cancer has a high rate of recurrence, frequent screenings are recommended. Normally, screenings would be needed every three to six months for the first three years, and every year after that, or as the physician considers necessary. **Cystoscopy** can catch a recurrence before it progresses to invasive cancer, which is difficult to treat.

Risks

All surgery carries some risk due to heart and lung problems or the **anesthesia** itself, but these risks are generally extremely small. The risk of death from general anesthesia for all types of surgery, for example, is only about 1 in 1,600. Bleeding and infection are other risks of any surgical procedure. If bleeding becomes a complication, bladder irrigation may be required postoperatively, during which time the patient's activity is limited to bed rest. Perforation of the bladder is another risk, in which case the urinary catheter is left in place for four to five days postoperatively. The patient is started on antibiotic therapy preventively. If the bladder is lacerated, accompanied by spillage of urine into the abdomen, an abdominal incision may be required.

Results

The results of transurethral bladder resection will depend on many factors, including the type of treatment used, the stage of the patient's cancer before surgery, complications during and after surgery, the age and overall health of the patient, as well as the recurrence of the disease at a later date. The chances for survival are improved if the cancer is found and treated early.

Morbidity and mortality rates

After a diagnosis of bladder cancer, up to 95% of patients with superficial tumors survive for at least five years. Patients whose cancer has grown into the lining of the bladder but not into the muscle itself, and is not in any lymph nodes or distant sites, have a five-year survival rate as high as 85%. The five-year survival rate may be as high as 55% for patients whose tumors have invaded the bladder muscle, but not spread through the muscle into the surrounding fatty tissue. When the cancer has grown totally through the bladder muscle into the surrounding fatty tissue, and perhaps into nearby tissues such as the prostate, uterus, or vagina, the five-year survival rate is about 38%. For patients whose cancer has spread through the bladder wall to the pelvis or abdominal wall or has spread distantly to lymph nodes or other organs (such as the bones, liver, or lungs), the five-year survival rate is 16%.

The five-year survival rate refers to the percentage of patients who live at least five years after their cancer is found, although many people live much longer. Five-year relative survival rates do not take into account patients who die of other diseases. Every person's situation is unique and the statistics cannot predict exactly what will happen in every case; these numbers provide an overall picture.

Mortality rates are two to three times higher for men than women. Although the incidence of bladder cancer in the Caucasian population exceeds that of the African American population, African American women die from the disease at a greater rate. This is due to a larger proportion of these cancers being diagnosed and treated at an earlier stage in the Caucasian population. The mortality rates for Hispanic and Asian men and women are only about one-half those for Caucasians and African Americans. Over the past 30 years, the age-adjusted mortality rate has decreased in both races and genders. This may be due to earlier diagnosis, better therapy, or both.

Alternatives

Surgery, radiation therapy, immunotherapy, and **chemotherapy** are the main types of treatment for cancer of the bladder. One type of treatment or a combination of these treatments may be recommended, based on the stage of the cancer.

After the cancer is found and staged, the cancer care team discusses the treatment options with the patient. In choosing a treatment plan, the most significant factors to consider are the type and stage of the cancer. Other factors to consider include the patient's overall physical

health, age, likely side effects of the treatment, and the personal preferences of the patient.

In considering treatment options, a second opinion may provide more information and help the patient feel more confident about the treatment plan chosen.

Alternative methods are defined as unproved or disproved methods, rather than evidence-based or proven methods to prevent, diagnose, and treat cancer. For some cancer patients, conventional treatment is difficult to tolerate and they may decide to seek a less unpleasant alternative. Others are seeking ways to alleviate the side effects of conventional treatment without having to take more drugs. Some do not trust traditional medicine, and feel that with alternative medicine approaches, they are more in control of making decisions about what is happening to their bodies.

A cancer patient should talk to the doctor or nurse before changing the treatment or adding any alternative methods. Some methods can be safely used along with standard medical treatment. Others may interfere with standard treatment or cause serious side effects.

The American Cancer Society (ACS) encourages people with cancer to consider using methods that have been proven effective or those that are currently under study. They encourage people to discuss all treatments they may be considering with their physician and other healthcare providers. The ACS acknowledges that more research is needed regarding the safety and effectiveness of many alternative methods. Unnecessary delays and interruptions in standard therapies could be detrimental to the success of cancer treatment.

At the same time, the ACS acknowledges that certain complementary methods such as **aromatherapy**, **biofeedback**, **massage therapy**, **meditation**, tai chi, or **yoga** may be very helpful when used in conjunction with conventional treatment.

Health care team roles

Transurethral bladder resections are usually performed in a hospital by a urologist, a medical doctor who specializes in the diagnosis and treatment of diseases of the urinary systems in men and women and also treats structural problems, tumors, and stones in the urinary system. Urologists can prescribe medications and perform surgery. If a transurethral bladder resection is required by a female patient, and there are complicating factors, an urogynecologist may perform the surgery. Urogynecologists treat urinary problems involving the female reproductive system.

Transvaginal ultrasound

Definition

Transvaginal **ultrasound** is an imaging technique used to create a picture of the genital tract in women. The hand-held device that produces the ultrasound waves is inserted directly into the vagina, close to the pelvic structures, often producing a clearer and less distorted image than obtained through transabdominal ultrasound technology, where the probe is located externally on the skin of the abdomen.

WWW.BOOKBAZ.IR

Purpose

Transvaginal ultrasound can be used to evaluate problems or abnormalities of the female genital tract. It may provide more accurate information than transabdominal ultrasound for women who are obese, for women who are being evaluated or treated for **infertility**, or for women who have difficulty keeping a full bladder. However, it does provide a view of a smaller area than the transabdominal ultrasound. Types of conditions or abnormalities that can be examined include:

- the endometrium of women with infertility problems or who are experiencing abnormal bleeding
- sources of unexplained pain
- congenital malformations of the ovaries and uterus
- ovarian cysts and tumors
- pelvic infections, such as pelvic inflammatory disease
- bladder abnormalities
- a misplaced IUD (intrauterine device)
- other causes of infertility

Transvaginal ultrasound can also be used during **pregnancy**. Its capability of producing more complete images means that it is especially useful for identifying **ectopic pregnancy**, fetal heartbeat, and abnormalities of the uterus, placenta, and associated pelvic structures.

Transvaginal ultrasound is performed by an ultrasound technologist, who is supervised by a radiologist or a specialist such as an obstetrician.

Precautions

Studies have shown that ultrasound is not hazardous and has no harmful side effects.

Description

A ultrasound, or sonogram, is a procedure that utilizes reflected sound waves to produce a picture of organs and structures within the body. A transducer sends out high-pitched sounds, sounds that are above the range of human hearing, that are reflected back to the transducer. A computer is used to analyze the sound waves, transforming them into a picture (called a sonogram, echogram, or ultrasound scan) on a video monitor. These pictures can be saved as a permanent record of the test.

A transvaginal ultrasound is used for looking at organs and structures within the pelvic area that are solid and uniform, like the uterus, and ovaries, or for organs that are fluid-filled, like the bladder. Mineralized structures, like bones, or air-filled organs, such as the intestines, do not show up well on a sonogram and may disrupt the ultrasound beam so that deeper organs and structures cannot be seen clearly.

The transvaginal transducer that produces the ultrasound waves is shaped to fit within a woman's vagina. It is lubricated and covered with a sheath such as a condom. A woman should tell the healthcare provider if she is allergic to latex so that a latex-free cover can be applied to the transducer before it is inserted into the vagina.

Sometimes a woman may have both transvaginal and transabdominal ultrasound scans done to obtain a complete evaluation of the pelvic area.

Preparation

There is no special preparation required by a woman before a transvaginal ultrasound. She can continue to take medications prescribed by her healthcare provider, although she should not drink liquids for four hours before the test. A full bladder is not required for a transvaginal ultrasound, as is required for a transabdominal ultrasound. The test can be administered during any stage of the woman's menstrual cycle.

During the procedure, the woman lies on her back, with her hips slightly raised. The thin, lubricated tip of the transducer is inserted gently into the vagina. The transducer is moved and rotated to adjust the view of the pelvic structures displayed on the monitor. The woman must lie very still during the ultrasound scan. She may feel a mild discomfort from the pressure of the vaginal transducer. The procedure usually takes 15–30 minutes.

Occasionally, **hysterosonography** is done on a nonpregnant woman to evaluate the inside of the uterus (endometrial cavity) and fallopian tubes by filling the uterus with fluid during a transvaginal ultrasound.

Aftercare

There is a slight risk of infection associated with a transvaginal ultrasound, especially if a biopsy was done in conjunction with the procedure. The patient should be aware of symptoms of an infection and seek care from a healthcare professional as necessary.

Risks

Since no ionizing radiation is associated with transvaginal ultrasound, there has been no documented adverse effects on patients or their fetuses with the use of the procedure.

KEY TERMS

Ectopic pregnancy—Pregnancy that develops outside the uterus, usually in one of the fallopian tubes.

Endometrium—The mucous membrane that makes up the inner layer of the uterine wall.

Gestational trophoblastic disease—A rare, aggressive, malignant, often metastatic (spreading to other organs) cancer in women of childbearing age in which cancer cells grow in the tissues that are formed in the uterus after conception.

Intrauterine device (IUD)—Contraceptive device consisting of a piece of bent plastic or metal that is inserted through the vagina into the uterus.

Transabdominal ultrasound—A small handheld instrument called a transducer is passed back and forth over the pelvic area to provide images of the abdomen.

Ovarian torsion—Twisting of the ovary due to the influence of another condition or disease, resulting in extreme lower abdominal pain.

Pelvic inflammatory disease (PID)—Inflammation of the female genital tract, especially of the fallopian tubes, caused by any of several microorganisms, chiefly chlamydia and gonococci, and characterized by severe abdominal pain, high fever, vaginal discharge, and in some cases destruction of tissue that can result in sterility.

Placenta previa—A low-lying placenta that covers part or all of the inner opening of the cervix. This can result in heavy bleeding during labor and delivery, which can be dangerous for mother and baby.

Placental abruption—Premature separation of the placenta from the uterus.

Results

In a normal transvaginal ultrasound, the pelvic structures or organs or the fetus are found to have no abnormalities.

Abnormal results

Abnormal ultrasound results can be due to a variety of conditions and diseases. In non-pregnant women, these abnormal results may include:

- cancerous tumors or non-cancerous growths of the uterus, ovaries, vagina, or other pelvic structures
- ovarian torsion
- infections such as PID
- congenital malformations

In pregnant women, the following abnormalities may be diagnosed through transvaginal ultrasound:

- ectopic pregnancies
- multiple pregnancies
- fetal death
- short cervix length, which may indicate the risk of preterm labor
- placental abnormalities such as placental previa and placental abruption
- tumors of pregnancy, including gestational trophoblastic disease

A biopsy is needed to determine whether a tumor that is found during the transvaginal ultrasound scan is cancerous or non-cancerous.

Transverse myelitis

Definition

Transverse myelitis (TM) is an uncommon neurological syndrome caused by inflammation (a protective response that includes swelling, **pain**, heat, and redness) of the spinal cord, characterized by weakness, back pain, and bowel and bladder problems. It affects one to five persons per million.

Description

TM affects the entire thickness of the spinal cord, producing both sensory and movement problems. It is believed to be linked to the immune system, which may be prompted to attack the body's own spinal cord. Striking rapidly without warning, its effects can be devastating.

WWW.BOOKBAZ.IR

Causes and symptoms

Transverse myelitis has many different causes, often triggered by a variety of viral and bacterial infections (especially those associated with a rash such as **measles** or **chickenpox**). Once the infection subsides, the inflammation in the cord begins. About a third of patients experience a flu-like illness with **fever** about the time they develop symptoms of TM. Sometimes, there appears to be a direct invasion of, and injury to, the spinal cord by an infectious agent (such as herpes zoster or the **AIDS** virus).

TM can also accompany a variety of diseases that break down tissue that surrounds and insulates the nerves (demyelinating diseases), such as **multiple sclerosis** (MS).

Some toxic substances, such as carbon monoxide, lead, or arsenic, can cause a type of myelitis characterized by inflammation followed by hemorrhage or bleeding that destroys the entire circumference of the spinal cord. Other types of myelitis can be caused by poliovirus; herpes zoster; **rabies**, **smallpox** or polio-vaccination; or parasitic and **fungal infections**.

Many experts believe that TM can occur without any apparent cause, probably as the result of an autoimmune process. This means that a person's immune system attacks the spinal cord, causing inflammation and tissue damage.

Regardless of the cause of the myelitis, onset of symptoms is sudden and rapid. Problems with movement and sensation appear within one or two days after inflammation begins. Symptoms include soft (flaccid) **paralysis** of the legs, with pain in the lower legs or back, followed by loss of feeling and sphincter (muscles that close an opening, as in the anus) control. The earliest symptom may be a girdle-like sensation around the trunk.

The extent of damage occuring will depend on how much of the spinal cord is affected, but TM rarely involves the arms. Severe spinal cord damage also can lead to **shock**.

Diagnosis

A doctor will suspect TM in any patient with a rapid onset of paralysis. Medical history, **physical examination**, brain and spinal cord scans, myelogram, spinal tap, and blood tests are used to rule out other neurological causes of symptoms, such as a tumor. If none of these tests suggest a cause for the symptoms, the patient is presumed to have transverse myelitis.

KEY TERMS

Demyelinating disorders—A group of diseases characterized by the breakdown of myelin, the fatty sheath surrounding and insulating nerve fibers. This breakdown interferes with nerve function, and can result in paralysis. Multiple sclerosis is a demyelinating disorder.

Myelogram—An x-ray examination of the brain and spinal cord with the aid of a contrast dye, to look for tumors or spinal cord injury.

Treatment

There is no effective treatment for transverse myelitis, but any underlying infection must be treated. After this, the focus of care shifts from diagnosis and treatment to learning how to live with the effects of the syndrome. Patients are helped to cope psychologically with new limitations, and are given physical **rehabilitation**.

Physical adaptations include learning to cope with bowel and bladder control, sexuality, inability to control muscles (spasticity), mobility, pain, and activities of daily living (such as dressing).

As nerve impulses from the spinal cord are often scrambled and misinterpreted by the brain as pain, painkillers are given to ease discomfort. Antidepressants or anticonvulsants may also help.

Prognosis

The prognosis depends on how much of the cord was damaged. Some people recover completely, while others have lasting problems and need help in learning how to cope with activities of daily living. People who develop spastic reflexes early in the course of the condition are more likely to recover than those who do not. If spinal cord tissue death (necrosis) occurs, the chance of a complete recovery is poor. Most recovery occurs within the first three months. A certain percentage of patients with TM will go on to develop multiple sclerosis.

Trauma

Definition

The English word *trauma* (plural, traumata) is simply the Greek word for "wound" written in the letters of the Roman rather than the Greek alphabet. It is used to refer to both physical and psychological injuries. In medicine, trauma is a physical wound or injury, often sudden, resulting from a violent blow or accident. In psychiatry, the term refers to damage to the mind and emotions resulting from a single event or series of experiences that overwhelm a person's ability to cope or to integrate the memories and feelings associated with the traumatic event(s).

Demographics

Physical trauma is the sixth-leading cause of death worldwide and accounts for 10% of all human deaths. In the United States, traumatic injury is the leading cause of death for persons between the ages of 1 and 44, with about 180,000 trauma deaths each year. About two-thirds of these deaths are accidental.

Psychological traumata vary widely in frequency and severity in the general population. It is estimated that 50–90% of people in North America will undergo a traumatic experience at some point in life, but only 7–8% will develop **post-traumatic stress disorder** (PTSD) or a complex post-traumatic syndrome. The lifetime prevalence of **rape and sexual assault** is estimated at 15–20% for women and 3–5% for men, although many researchers maintain that rapes for both sexes are under-reported. With regard to child **sexual abuse**, 15–25% of women in North America and 5–15% of men report being sexually abused in childhood. In terms of combat-related trauma, about a quarter of the men and women deployed to Iraq and Afghanistan and during the Gulf War met or still meet the criteria for **acute stress disorder** (ASD) or PTSD.

Mass traumata, such as major industrial explosions, severe natural disasters, the loss of a large airplane or ship, or large-scale terrorist attacks, are rare but may have a disproportionate impact on survivors and first responders. Mass traumata are more likely to lead to survivor guilt, a condition in which a person feels that they did something wrong or should feel guilty about surviving a disaster when others did not.

Description

Psychological or psychiatric trauma has two dimensions, objective and subjective. It may or may not be associated with physical trauma; in general, physical traumata that cause permanent damage to the senses or other body functions, or that result in disfigurement (particularly to the face), are more likely to have psychological sequelae than those that heal completely. The objective aspect of psychological trauma is its external description or definition, such

as "rape," "airplane crash," or "earthquake." The subjective dimension is the survivor's experience of being overwhelmed and rendered helpless by the event or incident. It is the individual's subjective experience that defines the event as traumatic for that person.

Causes and symptoms

Different people tend to respond differently to the same traumatic event; for example, some survivors may develop PTSD, some may have a time-limited **stress** reaction, and others may appear to be unaffected. The type of traumatic event or incident, however, may have some effect on the victims' response:

- Intentional human-caused traumata (e.g., war, criminal assault, rape, or torture) can be more distressing than technological accidents (e.g., transportation disasters, oil spills, plant explosions) or natural disasters (e.g., floods, hurricanes, tornadoes, blizzards, earthquakes, or volcanic eruptions).
- Repeated stressors, such as physical or sexual abuse, domestic violence, and military combat, are more likely to lead to PTSD than single episodes of trauma, as are stressors of long duration (e.g., kidnapping, some natural disasters, or warfare). The National Cancer Institute (NCI) maintains that the duration of the illness and its treatment helps to explain the emergence of PTSD in cancer patients.
- Multifaceted traumata may be a greater risk factor for experiencing a trauma-related disorder than simple traumata. For example, a person caught in a tornado may witness the death of, or injury to, loved ones in addition to the loss of their home and personal possessions, and possibly their job, as well as physical injury to their own body.
- Traumata experienced in childhood are more likely to have long-term effects than those experienced in adult life.
- Unpredictable traumata (e.g., most industrial accidents, airplane and railroad crashes, or terrorist attacks) are more shocking than those that could be at least partly predicted or foreseen (e.g., hurricanes, tornadoes, or some epidemics) and may produce a more severe traumatic response.
- Traumata inflicted by a parent, caregiver, or other trusted adult may have a more serious effect on the victim than would similar actions inflicted by a stranger.

Post-traumatic stress disorder and acute stress disorder

PTSD and ASD are two of the more common disorders associated with trauma. Although the conditions are distinct, they do share some similar symptoms, including:

- flashbacks or recurring nightmares of the traumatic event
- avoidance of persons, places, or things that might spark a memory of the event
- a constant state of hyperarousal, a condition characterized by irritability, anxiety, insomnia, lack of concentration, and extreme startle response
- detachment from people or surroundings

Complex trauma

Complex trauma is a term with two different meanings, depending on whether it is applied to children or adults. According to the National Child Traumatic Stress Network, the term refers to a child's "exposure to multiple or prolonged traumatic events and the impact of this exposure on their development." Complex trauma in children may be either sequential or simultaneous and may include psychological maltreatment, neglect, physical and sexual **abuse**, and domestic violence. This type of trauma is chronic, begins in early childhood, and occurs within the primary caregiving system. It is estimated that about 30% of children nationwide in North America are exposed to complex trauma, and as many as 50% of children in some distressed communities; however, only about 12% of these children receive treatment. Rates of self-mutilation and nonsuicidal self-injury are as high as 62% among these children. Developmental trauma disorder (DTD) appears to be increasingly used as a synonym for complex trauma in children.

Complex trauma is also sometimes used to describe a condition in adults more accurately referred to as complex PTSD or C-PTSD. C-PTSD is a concept that Judith Herman developed in the 1997 edition of her book *Trauma and Recovery*. Herman maintained that the *DSM-IV* criteria for PTSD did not adequately account for the symptoms of survivors of chronic repetitive trauma, such as domestic violence, hostage situations, other forms of captivity, torture, or other abusive situations from which escape is difficult. Herman identified psychological fragmentation; the loss of a sense of safety, trust, and self-worth; a tendency to be revictimized; and insecure or disorganized forms of attachment to others as the symptoms that most clearly differentiate C-PTSD from PTSD. She also described three phases in the recovery of adults with C-PTSD: re-establishing a sense of safety, remembering and mourning what was lost in the traumatic experience, and reconnecting with the survivor's community and the larger society. Although some medical

journals have published papers on C-PTSD, the disorder was not recognized by *DSM-IV*, although it is possible that *DSM-5* could include it under the category of "Other specified trauma- or stressor-related disorder."

Rape trauma syndrome

Rape trauma syndrome (RTS) is a term first coined by Ann Burgess and Lynda Holmstrom in 1974 to describe a complex form of psychological trauma to a rape victim (male or female) reflected in disruptions of the survivor's emotional, cognitive, physical, and interpersonal behaviors. RTS is a syndrome with two phases, an acute phase that lasts from several days to several weeks after the assault, and a longer "reorganization phase." Survivors react in different ways during the acute phase. Some survivors are expressive, meaning that they show their emotions by crying, yelling, or being openly angry. Others are controlled; they may be completely silent about the rape and go about their daily routines as if nothing has happened. Neither type of response is considered superior to the other.

The second phase of RTS is the reorganization phase, in which the survivor tries to recover the sense of safety and ability to trust others that he or she had before the rape. The survivor must cope with intense feelings of guilt and shame as well as fear and **anxiety**. In some cases, the survivor may feel disconnected or dissociated from her or his body. Male survivors are more likely than females to have questions about their sexual identity and orientation; they are also more likely to postpone or avoid treatment. One study of 100 male rape survivors found that the average time interval between the assault and seeking therapy was 16 years.

In addition to the emotional symptoms of RTS, many survivors also experience a variety of physical symptoms ranging from tension headaches and generalized muscle **pain** to specific symptoms in the parts of the body that were penetrated during the assault. Survivors of oral rape may have a variety of mouth and throat complaints, **nausea and vomiting**, and bulimia or anorexia, while survivors of vaginal or anal rape may experience abdominal cramping, **dysmenorrhea**, **constipation**, or **diarrhea**.

Indirect trauma

Indirect trauma, also called vicarious trauma or empathic strain, is a condition that may develop in therapists and others who work with trauma survivors over long periods of time. The symptoms of indirect trauma are similar to those of survivors; the care provider may experience nightmares, intrusive thoughts, intense anxiety, avoidance behaviors, **sleep disorders**, difficulty regulating emotions, and disruptions in personal or professional relationships. Indirect trauma may also involve a form of survivor guilt, such as when first responders feel that they are to blame for not having rescued everyone from a disaster, or when a therapist feels guilty about not being able to relieve a patient's suffering quickly.

Diagnosis

The subjective aspect of psychological trauma complicates assessment and evaluation of trauma survivors. A person who thinks that he or she may have PTSD or another trauma-related disorder should consult a psychiatrist or other healthcare provider with special training in the assessment of trauma survivors. In addition, the person should ask whether the doctor specializes in the type of trauma that the survivor underwent, and whether the doctor is also experienced in assessing members of the survivor's age group. There are different tests or question sets that can be used to evaluate adult and child survivors for symptoms of a disorder, and it requires specialized training to decide which test to administer in a given case and then interpret the results.

DSM-IV and *DSM-5*

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, first published in 1994 and revised in 2000, defined two trauma-related disorders—PTSD and ASD—under the larger category of **anxiety disorders**. A third disorder associated with trauma, adjustment disorder, was placed in a separate category of its own. The *DSM-5*, published in 2013, has revised this classification, introducing a new category, titled Trauma- and Stressor-Related Disorders, which includes the three trauma-related disorders defined by *DSM-IV* plus five new diagnostic categories, three of which are restricted to children.

The eight disorders listed under the *DSM-5* category are as follows:

- Reactive attachment disorder of infancy or early childhood. This disorder was moved from the *DSM-IV* category of "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence" to the new diagnostic category.
- Disinhibited social engagement disorder. Previously defined as a subtype of reactive attachment disorder in *DSM-IV*, the diagnosis describes children who lack the normal ability to select appropriate attachment figures and demonstrate excessive familiarity with, or closeness to, relative strangers.

WWW.BOOKBAZ.IR

- Post-traumatic stress disorder in preschool children. This disorder is essentially a form of PTSD as found in children below the age of six years. Some of the criteria are similar to those for developmental trauma disorder, another proposed new diagnostic category.
- Acute stress disorder (ASD). The major revisions in *DSM-5* are the division of symptoms into four categories (intrusive, dissociative, avoidance, and arousal); the addition of "learning that the [traumatic] event(s) occurred to a close relative or close friend" as well as witnessing or experiencing the event oneself; and the specifier that "[the criterion of exposure] does not apply to exposure through electronic media, television, movies or pictures, unless this exposure is work-related."
- Post-traumatic stress disorder (PTSD). As with ASD, proposed changes include the addition of "learning that the [traumatic] event(s) occurred to a close relative or close friend" as well as witnessing or experiencing the event oneself; and the specifier that "[the criterion of exposure] does not apply to exposure through electronic media, television, movies or pictures, unless this exposure is work-related."
- Adjustment disorders. The major difference between the *DSM-IV* definition of adjustment disorder and the changes in *DSM-5* is the addition of a distinct subtype called *bereavement-related disorder*.
- Other specified trauma- or stressor-related disorder.
- Unspecified trauma- or stressor-related disorder.

Developmental trauma disorder

The *DSM-5* working group lists developmental trauma disorder (DTD) among the "Conditions Proposed by Outside Sources." The new diagnostic category has been discussed among experts in **child abuse** since the 1980s, on the grounds that the criteria for PTSD in adults fail to detect the symptoms of recurrent traumata in childhood, and that as a result, affected children do not receive proper treatment. Only 5–10% of children exposed to interpersonal abuse, domestic violence, and other recurrent dangers meet criteria for PTSD; however, over 50% of such children have problems with affect regulation, attention and concentration, negative self-image, impulse control, aggression, and risk-taking. As a result, the children are usually diagnosed as having one or more of a set of unrelated conditions, including **bipolar disorder**, **attention deficit hyperactivity disorder (ADHD)**, **conduct disorder**, phobic anxiety, reactive attachment disorder, and separation anxiety, and they are usually treated with medications only, rather than **psychotherapy**. The diagnostic category of "developmental trauma disorder" would allow clinicians to effectively recognize and treat the core symptoms in these children—impaired capacity for emotional and behavioral regulation, and attachment-related difficulties.

A tentative set of criteria for the disorder was drawn up by Bessel van der Kolk in 2005 and revised by the National Child Traumatic Stress Network (NCTSN) in 2009. There are seven criteria in the present proposal:

- A. Exposure. The child or adolescent has experienced or witnessed multiple or prolonged adverse events over a period of at least one year beginning in childhood or early adolescence, including direct experience or witnessing of repeated and severe episodes of interpersonal violence and disruption of protective caregiving as the result of repeated changes in primary caregiver, repeated separation from the primary caregiver, or exposure to severe and persistent emotional abuse.
- B. Affective and emotional dysregulation. The child or adolescent exhibits at least two of the following: inability to recover from states of fear, shame, or anger, including prolonged tantrums or immobility; problems with such bodily functions as eating, sleeping, and elimination; diminished awareness of emotions, sensations, or bodily states; and inability to vocalize emotions or sensations.
- C. Attentional and behavioral dysregulation. The child experiences at least three of the following: inability to focus attention appropriately; preoccupation with threats or, conversely, a failure to perceive them; active thrill-seeking or risk-taking; lack of goal-directed behavior; and repeated or habitual acts of self-harm.
- D. Self- and relational dysregulation. The child demonstrates at least three of the following: impaired sense of identity; preoccupation with caregiver's safety; extreme distrust of, or aggressive action toward, others; inappropriate attempts to seek intimacy with adults or peers, including, but not limited to, sexual or physical contact; excessive reliance on others for safety or reassurance; inability to show empathy for others in pain or, conversely, showing excessive distress.
- E. Post-traumatic symptoms. The child shows at least one symptom in two of the three symptom clusters of adult PTSD (criteria B, C, and D).
- F. Duration. The symptoms in criteria B, C, D, and E must be present for at least six months.
- G. Functional impairment. The child has clinically significant distress or impaired function in at least two of six areas: academic, family, peer group, legal

system, physical health, and vocational preparation or planning.

Treatment

Treatment for trauma-related disorders usually involves a combination of approaches rather than a single form of treatment. In addition, a person in an ongoing traumatic situation, such as a violent family situation or abusive relationship, needs to be removed from the traumatic environment prior to therapy in order for treatment to be effective.

There are several different forms of psychotherapy that are used in the treatment of trauma survivors. According to the National Institute of Mental Health (NIMH), psychotherapy for adults with PTSD and acute stress disorder usually lasts 6–12 weeks but may take longer. Therapies include:

- Cognitive-behavioral therapy (CBT). CBT may include exposure therapy, in which the survivor is exposed in a safe place to situations or images that they are avoiding, as reminders of the trauma; cognitive restructuring (sometimes called "cognitive processing" therapy when used to treat survivors of PTSD), in which the survivor learns to reframe memories of the traumatic event, particularly those that lead to feelings of guilt or shame; and stress inoculation training, in which the survivor learns to identify the cues that trigger traumatic memories and to cope with them by using relaxation and deep-breathing techniques.
- Psychodynamic psychotherapy. This approach is helpful to survivors with unresolved issues from childhood or adolescence that resurfaced as a result of the traumatic experience. It may be combined with CBT.
- Group therapy and family therapy. These approaches are often recommended for survivors of specific traumata (e.g., rape, combat, workplace violence, or accidents) or mass disasters.
- Supportive therapy. This therapy refers to any form of treatment intended to relieve the patient's symptoms rather than to bring about changes in the patient's behaviors or basic character structure.

There were 120 clinical trials underway as of mid-2011 for various medications and psychotherapy in the treatment of psychological trauma, and an additional eight studies of medications (topiramate and risperidone) or cognitive processing therapy for women with rape trauma syndrome.

Therapists and other healthcare providers affected by indirect trauma are advised to consult a supervising therapist or another specialist in trauma treatment if self-care—activities such as getting adequate rest; eating a healthful diet; balancing their trauma work with other work; getting support from friends, family, and colleagues; and acknowledging the difficulties of the work—do not help.

Drugs

Medications for trauma- and stressor-related disorders include the **selective serotonin reuptake inhibitors** (SSRIs); mood stabilizers like valproate (Depakote), carbamazepine (Tegretol), and topiramate (Topamax) to treat flashbacks, nightmares, and other symptoms of hyperarousal; and benzodiazepine tranquilizers to treat sleep disorders. The only two SSRIs specifically approved by the U.S. Food and Drug Administration (FDA) for the treatment of PTSD are sertraline (Zoloft) and paroxetine (Paxil). Other SSRIs that may be prescribed include fluoxetine (Prozac) and citalopram (Celexa). However, it is important for trauma survivors with a coexisting substance abuse disorder to be treated for that before being given any psychoactive drugs.

Alternatives

One form of complementary therapy that is often recommended to trauma survivors is relaxation training. Sometimes called anxiety management training, relaxation training includes breathing exercises and similar techniques intended to help the patient prevent hyperventilation and relieve the muscle tension associated with the fight-or-flight reaction of anxiety. **Yoga**, aikido, tai chi, and other forms of **movement therapy** are also reported to help patients work with the physical as well as the emotional tensions that are associated with trauma-related anxiety.

Other complementary therapies that are reported to relieve the symptoms of PTSD and other trauma-related disorders include **massage therapy**, **art therapy**, journaling, and **music therapy**. However, there is little research support for these therapies.

Some trauma survivors benefit from spiritual or religious counseling. Because traumatic experiences often affect people's spiritual views and beliefs, counseling with a trusted religious or spiritual advisor may be part of a treatment plan. A growing number of pastoral counselors in the major Christian and Jewish bodies in North America have advanced credentials in trauma therapy. Native Americans are often helped to recover from PTSD by participating in traditional

Dissociation—Partial or complete disruption of a person's normal memory and psychological functioning. Dissociative symptoms are commonly experienced by persons with PTSD.

Indirect trauma—A term used to refer to symptoms of trauma in therapists, first responders, and others who treat trauma survivors. It is sometimes called vicarious trauma.

Polytrauma—The medical term for injury to more than one part of the body or more than one type of injury (such as burn injuries in addition to broken bones).

tribal rituals for cleansing memories of war and other traumatic events. These rituals may include sweat lodges, prayers and chants, or consultation with a shaman or tribal healer.

Treatment of mass trauma

Treatment of survivors of a mass accident or disaster is different from treating survivors of an individual or small-scale attack or event. While most people in mass critical events can be helped by getting to safety, obtaining food and water, getting medical help if injured, contacting loved ones, and getting accurate information about what is being done to help, some survivors do not get better on their own after a mass disaster and may even find their depression or PTSD becoming worse with time. One reason for this phenomenon is widespread destruction of the community's infrastructure (e.g., buildings, roads, bridges, railroads, water supply, or airports), often involving loss of jobs, schools, and basic housing as well as difficulty finding healthcare, purchasing food, or paying bills. In many cases, families may have to move to a different location hundreds of miles away. Hospitals and trauma centers in the affected area may be overwhelmed by the scale of the disaster, meaning that some survivors do not receive the psychological or physical care they need in a timely fashion, especially when doctors and other healthcare providers may be struggling with their own injuries, lack of supplies and transportation, and emotional reactions to the situation.

One approach to psychotherapy following mass trauma that is still considered experimental is the use of Internet- and phone-based therapy to treat survivors who could not be assessed immediately following the disaster.

Prognosis

There is considerable discussion among psychiatrists and other therapists regarding the classification of different types of psychological traumata, particularly in regard to complex forms of traumatization and the specification of the age group affected. There is a

growing recognition that trauma affects the development and maturation of children and adolescents in a variety of ways; that symptoms in children and adolescents differ from those in adults; and that proper diagnosis of young survivors is essential to effective treatment. At present, researchers have not reached agreement on the most appropriate names for trauma-related disorders, their diagnostic criteria, or their relationship to other mental disorders.

Traumatic amputations

Definition

Traumatic **amputation** is the accidental severing of some or all of a body part. A complete amputation totally detaches a limb or appendage from the rest of the body. In a partial amputation, some soft tissue remains attached to the site.

This man's hand was surgically reattached following a traumatic amputation. *(Custom Medical Stock Photo, Inc.)*

Description

Trauma is the second leading cause of amputation in the United States. About 30,000 traumatic amputations occur in this country every year. Four of every five traumatic amputation victims are male, and most of them are between the ages of 15–30.

Traumatic amputation most often affects limbs and appendages like the arms, ears, feet, fingers, hands, legs, and nose.

Causes and symptoms

Farm and factory workers have greater-than-average risks of injuries that result in traumatic amputation. Automobile and motorcycle accidents and the use of lawnmowers, saws, and power tools are also common causes of traumatic amputation.

Blood loss may be massive or minimal, depending on the nature of the injury and the site of the amputation. Patients who lose little blood and have less severe injuries sometimes feel more **pain** than patients who bleed heavily and whose injuries are life-threatening.

Diagnosis

When the patient and the amputated part(s) reach the hospital, an Emergency Department physician will assess the probability that the severed tissue can be successfully reattached.

The Mangled Extremity Severity Score (MESS) assigns numerical values to such factors as body temperature, circulation, numbness, **paralysis**, tissue health, and the patient's age and general health. This is one of the diagnostic tools used to determine how successful reattachment surgery is apt to be. The total score is doubled if blood supply to the amputated part has been absent or diminished for more than six hours.

A general, emergency, or orthopedic surgeon makes the final determination about whether surgery should be performed. The surgeon also considers the patient's wishes and lifestyle. Additional concerns are how and to what extent the amputation will affect the patient's quality of life and ability to perform everyday activities.

Treatment

First aid or emergency care given immediately after the amputation has a critical impact on both the physicians' ability to salvage and reattach the severed part(s) and the patient's ability to regain feeling and function.

Muscle tissue dies quickly, but a well-preserved part can be successfully reattached as much as 24 hours after the amputation occurs. Tissue that has not been preserved will not survive for more than six hours.

Initial response

The most important steps to take when a traumatic amputation occurs are:

- Contact the nearest emergency services provider, clearly describe what has happened, and follow any instructions given.
- Make sure the victim can breathe; administer CPR if necessary.
- Control bleeding, using direct pressure but minimizing or avoiding contact with blood and other body fluids.
- Patients should not be moved if back, head, leg, or neck injuries are suspected or if motion causes pain. If none are found by the EMT, lie the victim flat, with the feet raised 12 in. (30 cm) above the surface.
- Cover the victim with a coat or blanket to prevent shock.

KEY TERMS

Phantom pain—Pain, tingling, itching, or numbness in the place where the amputated part used to be.

The injured site should be cleansed with a sterile solution and wrapped in a clean towel or other thick material that will protect the wound from further injury. Tissue that is still attached to the body should not be forced back into place. If it cannot be gently replaced, it should be held in its normal position and supported until additional care is available.

Saving the patient's life is always more important than recovering the amputated part(s). Transporting the patient to a hospital or emergency center should never be delayed until missing pieces are located.

Preserving tissue

No amputated body part is too small to be salvaged. Debris or other contaminating material should be removed, but the tissue should not be allowed to get wet.

An amputated body part should be wrapped in bandages, towels, or other clean, protective material and sealed in a plastic bag. Placing the sealed bag in a cooler or in a container that is inside a second container filled with cold water or ice will help prevent tissue deterioration.

Prognosis

Possible complications of traumatic amputation include:

- excessive bleeding
- infection
- muscle shortening
- pulmonary embolism

Improved medical and surgical care and **rehabilitation** have improved the long-term outlook for these patients.

Phantom pain

About 80% of all amputees over the age of four experience tingling, **itching**, numbness, or pain in the place where the amputated part used to be. Phantom sensations may begin immediately after the amputation, or they may develop months or years later. They often occur after an injury to the site of the amputation.

WWW.BOOKBAZ.IR

These intermittent feelings may:

- occur frequently or only once in a while
- be mild or intense
- last for a few minutes or several hours
- help patients adjust more readily to an artificial limb (prosthesis).

Prevention

The best way to prevent traumatic amputation is to observe common-sense precautions like using seat belts and obeying speed limits and other traffic regulations. It is important to take special precautions when using potentially dangerous equipment and make sure machinery is turned off and disconnected before attempting to service or repair it. Appropriate protective clothing should be worn at all times.

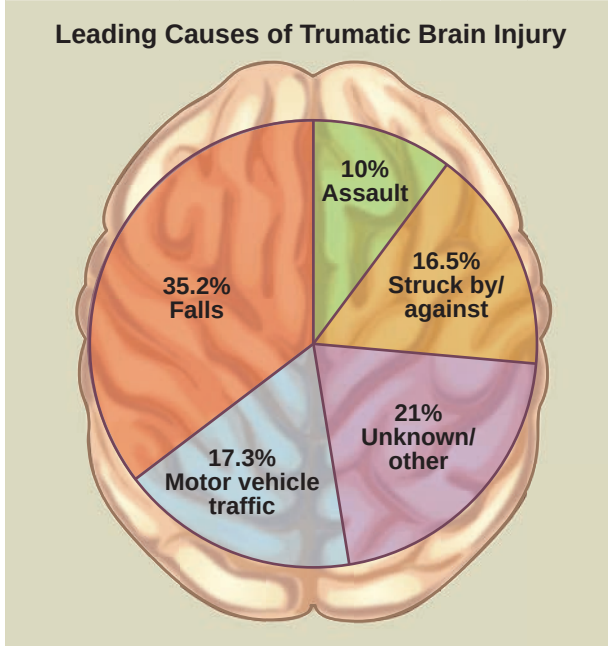
Traumatic brain injury

Definition

Traumatic brain injury (TBI) is a physical injury to brain tissue that temporarily or permanently impairs brain function. TBI is sometimes known as acquired brain injury. TBIs can be evaluated as mild, moderate, or severe, depending on whether the person was knocked out and how long they were unconscious. In a mild TBI, also known as a **concussion**, the person either does not lose consciousness at all or is unconscious for 30 minutes or less. In a moderate TBI, the person is unconscious longer than 30 minutes but less than 6 hours. Unconsciousness lasting longer than 6 hours indicates a severe TBI.

Demographics

Estimates for the number of Americans affected by TBI vary. One source estimates that the number of persons in the United States who have had a TBI ranges between 2.5 and 6.5 million, making it a major **public health** problem that costs the country more than $48 billion annually. Yearly estimates range from 180–220 cases per 100,000 population, or 600,000 TBIs annually. As many as 10% of these injuries are fatal, resulting in almost 550,000 persons hospitalized annually in the United States with head injuries. According to the U.S. Centers for Disease Control and Prevention (CDC), 52,000 individuals die from traumatic brain injuries each year in the United States, with almost twice that number having permanent disability. TBI is a contributing factor in 30% of all injury-related deaths in North America. Since 75% of head injuries are classified as mild, it is likely that many mild injuries go unreported.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

With regard to sex and race, in North America, males are twice as likely to be hospitalized for a TBI as females. This sex ratio in found worldwide. African Americans and Native Americans have higher rates of TBIs than other ethnic groups in the United States. With regard to age, half of all hospital admissions for TBIs involve people 24 years of age or younger.

Infants, children under five years of age, and adults 75 years and older are also at higher risk for TBI than the general population because they are most susceptible to falls around the home. Other factors predisposing the very young and the very old to TBI

include physical **abuse**, such as violent shaking of an infant or toddler known as **shaken baby syndrome**.

Description

No two brain injuries are exactly the same; TBIs vary greatly in regard to changes in brain structure as well as severity. Mild TBIs may produce only microscopic changes in the structure of the brain, while severe TBIs may produce gross (major) damage. The nature and extent of injury depend on the mechanism of the injury and the amount of force involved. There are three main types of brain injuries: contusions (bruising of the brain tissue), axonal injuries (injuries to the axons, the long slender projects of nerve cells that carry nerve impulses away from the body of the cell), and hematomas (bleeding in the brain).

Immediate complications of TBI may include seizures, enlargement of the fluid-filled chambers within the brain (**hydrocephalus** or post-traumatic ventricular enlargement), leaks of cerebrospinal fluid, infection, injury to blood vessels or to the nerves supplying the head and neck, **pain**, bed sores, failure of multiple organ systems, and **trauma** to other areas of the body.

Long-term survivors of a TBI may have persistent problems with behavior, thinking, and communication disabilities, as well as **epilepsy**; loss of sensation, hearing, vision, taste, or smell; ringing in the ears (**tinnitus**); coordination problems; and/or **paralysis**. Recovery from cognitive deficits is most dramatic within the first six months after TBI, and less apparent subsequently.

Risk factors

Risk factors for TBIs include:

- age—children younger than 4 years, adolescents between 16 and 19, and adults over 65 are at increased risk
- male sex
- African American, Native American, or Hispanic ethnicity
- participation in contact sports, diving, or mountain climbing
- employment in construction, mining, and other occupations requiring blasting or wearing a hard hat
- frontline military combat
- drug or alcohol abuse
- driving under the influence of drugs or alcohol

Causes and symptoms

Causes

The causes of TBIs are commonly classified as either closed- or open-head injuries. Either type of injury may cause direct damage to brain tissue (crushing or tearing of brain tissue itself), or the damage may result from the cascade of events resulting from the original injury. In some cases, there is increased intracranial pressure (ICP), resulting from the fact that the skull is a closed space filled with cerebrospinal fluid that cannot be compressed and brain tissue that allows only minimal compression. Any swelling from **edema** or a hematoma inside the skull leads to a rise in the ICP. This process reduces the amount of blood flow to the brain, which in turn can lead to ischemia (inadequate blood supply) of the brain tissue.

CLOSED-HEAD INJURIES. A closed **head injury** is a type of TBI in which the head is hit by or strikes an object without breaking the skull. In a penetrating head injury, an object such as a bullet **fractures** the skull and enters brain tissue.

Diffuse brain damage associated with closed head injury may result from back-and-forth movement of the brain against the inside of the bony skull. This is sometimes called coup-contrecoup injury. "Coup," French for "blow," refers to the brain injury directly under the point of maximum impact to the skull. "Contrecoup," French for "opposite the blow," refers to the brain injury opposite the point of maximum impact. Coup-contrecoup injury may occur in a rear-end collision, with high-speed stops, or with violent shaking of a baby, because the brain and skull are of different densities and, therefore, travel at different speeds. The impact of the collision causes the soft, gelatinous brain tissue to jar against bony ridges on the inside of the skull.

Because of the movement of these injuries and the position of the brain within the skull, the frontal lobes (behind the forehead) and temporal lobes (underlying the temples) are most susceptible to this type of diffuse damage. These lobes house major brain centers involved in speech and language, so problems with communication skills often follow closed head injuries of this type.

Depending on which areas of the brain are injured, other symptoms of closed head injury may include difficulty with concentration, memory, thinking, swallowing, walking, balance, and coordination; weakness or paralysis; changes in sensation; and alteration of the sense of smell.

WWW.BOOKBAZ.IR

The consequences of a TBI can be relatively subtle or completely devastating, depending on the severity and mechanism of injury. Diffuse axonal injury (DAI), or shear injury, may follow contrecoup injury even when there is no damage to the skull or obvious bleeding into the brain tissue. A DAI involves damage to the axon, which is the part of the nerve that communicates with other nerves. The injured axon degenerates and releases harmful substances that can damage neighboring nerves. DAI is typically the underlying injury in shaken baby syndrome.

SKULL FRACTURES. Skull fractures caused by severe blunt trauma are considered a type of open-head injury. When the skull cracks or breaks, the resulting skull fracture can cause a contusion—an area of bruising of brain tissue associated with swelling and blood leaking from broken blood vessels. A depressed skull fracture occurs when fragments of the broken skull sink or are pushed downward from the skull surface and press against the surface of the brain. In a penetrating skull fracture, bone fragments enter brain tissue. Either type of skull fracture can cause bruising of the brain tissue, called a contusion. Contrecoup injury can also lead to brain contusion.

Some skull fractures are likelier than others to lead to a severe TBI. They include:

- Skull fractures in persons who already have a neurological disorder or impairment.
- Depressed skull fractures.
- Fractures of the occipital bone and the basilar bones of the skull. The basilar bones are strong, thick bones that require a very strong impact to break them, which implies a force strong enough to cause significant damage to the brain tissue itself.
- Fractures in infants. There is a risk of the fracture widening as the baby's skull is still growing.
- Fractures involving the carotid canal. The carotid canal is a passageway through the temporal bone of the skull that allows the internal carotid artery to enter the skull. A fracture in the area of the carotid canal can result in dissection of the carotid artery.

HEMATOMAS. If the physical trauma to the head ruptures a major blood vessel, the resulting bleeding into or around the brain is called a hematoma. Bleeding between the skull and the dura, the thick, outermost layer covering the brain, is termed an epidural hematoma. When blood collects in the space between the dura and the arachnoid membrane, a more fragile covering underlying the dura, it is known as a **subdural hematoma**. An intracerebral hematoma involves bleeding directly into the brain tissue.

All three types of hematomas can damage the brain by putting pressure on vital brain structures. Intracerebral hematomas can cause additional damage as toxic breakdown products of the blood harm brain cells, cause swelling, or interrupt the flow of cerebrospinal fluid around the brain.

EXTERNAL CAUSES. Transportation accidents involving automobiles, motorcycles, bicycles, and pedestrians account for half of all TBIs and for the majority of TBIs in individuals under the age of 75. At least half of all TBIs are associated with alcohol use. **Sports injuries** cause about 3% of TBIs; other accidents leading to TBI may occur at home, at work, or outdoors.

In those aged 75 and older, falls are responsible for most TBIs. Other situations leading to TBI at all ages include violence, implicated in about 20% of TBIs. Firearm assaults are involved in most violent causes of TBI in young adults, whereas **child abuse** is the most common violent cause in infants and toddlers. In shaken baby syndrome, a baby is shaken with enough force to cause severe countrecoup injury.

Symptoms

Symptoms, complaints, and neurological or behavioral changes following TBI depend on the location(s) of the brain injury and on the total volume of injured brain. Usually, TBI causes focal brain injury involving a single area of the brain where the head is struck or where an object such as a bullet enters the brain. Although damage is typically worst at the point of direct impact or entry, TBI may also cause diffuse brain injury involving several other brain regions.

The symptoms of TBI may occur immediately or they may develop slowly over several hours, especially if there is slow bleeding into the brain or gradual swelling. Depending on the cause, mechanism, and extent of the injury, the severity of immediate symptoms of TBI can be mild, moderate, or severe, ranging from mild concussion to deep **coma** or even death.

With concussion, the injured person may experience a brief or transient loss of consciousness, much like **fainting** or passing out, or merely an alteration in consciousness described as "seeing stars" or feeling dazed or "out of it." At the other extreme, coma refers to a profound or deep state of unconsciousness in which the individual does not respond to the environment in any meaningful way.

Approximately 40% of patients with TBI develop postconcussion syndrome within days to weeks, with symptoms including **headache**, **dizziness** or a sensation of spinning (vertigo), memory problems, trouble

concentrating, sleep disturbances, restlessness, irritability, depression, and **anxiety**. This syndrome may persist for a few weeks, especially in patients with depression, anxiety, or other psychiatric symptoms before the TBI.

With more severe injuries, there may also be immediate numbness or weakness of one or more limbs, blindness, deafness, inability to speak or understand speech, slurred speech, lethargy with difficulty staying awake, persistent **vomiting**, loss of coordination, disorientation, or agitation. In addition to some of these symptoms, young children with moderate to severe TBI may also experience prolonged crying and refusal to nurse or eat.

When a person with a TBI regains consciousness, some symptoms are immediately apparent, while others are not noticed until several days or weeks later. Symptoms that may be obvious right away after mild TBI include headache, changes in vision such as blurred vision or tired eyes, nausea, dizziness, lightheadedness, ringing in the ears, bad taste in the mouth, or altered sense of smell, which is usually experienced as loss of the sense of taste.

While the injured person is preoccupied with headache or pain related to other physical trauma, symptoms such as difficulty in thinking or concentrating may not be evident. Often these more subtle symptoms may appear only when the individual attempts to return to work or to other mentally challenging situations. Similarly, personality changes, depression, irritability, and other emotional and behavioral problems may initially be attributed to coping with the **stress** of the injury, and their severity may not be fully recognized until the individual is recuperating at home. Other symptoms that may appear immediately or that may be noticed only while the individual is returning to usual activities are confusion, **fatigue** or lethargy, altered sleep patterns, and trouble with memory, concentration, attention, and finding the right words or understanding speech. Seizures may occur soon after a TBI or may first appear up to a year later, especially when the damage involves the temporal lobes.

Diagnosis

Diagnosis of a TBI is suspected on the basis of the clinical signs and symptoms and confirmed by diagnostic imaging.

Examination

Recognizing a serious head injury, starting basic **first aid**, and seeking emergency medical care can help the injured person avoid disability or even death. When encountering a potential TBI, helpers on the scene should try to find out what happened from the injured person, from clues at the scene, and from any eyewitnesses. Because **spinal cord injury** often accompanies serious head trauma, it is prudent to assume that there is also injury to the spinal cord and to avoid moving the person until the paramedics arrive. Spinal cord injury is a challenging diagnosis; nearly one-tenth of spinal cord injuries accompanying TBI are initially missed.

Signs apparent to the observer that suggest serious head injury and mandate emergency treatment include shallow or erratic breathing or pulse; a drop in blood pressure; broken bones or other obvious trauma to the skull or face such as bruising, swelling, or bleeding; one pupil being larger than the other; or clear or bloody fluid drainage from the nose, mouth, or ears.

Symptoms reported by the injured person that should also raise red flags include severe headache, stiff neck, vomiting, paralysis or inability to move one or more limbs, blindness, deafness, or inability to taste or smell. Other ominous developments may include initial improvement followed by worsening symptoms, deepening lethargy or unresponsiveness, personality changes including irritability or unusual behavior, or loss of coordination.

When emergency personnel arrive, they will stabilize the patient, evaluate the patient's signs and symptoms, and assess the nature and extent of other injuries, such as broken bones, spinal cord injury, or damage to other organ systems. Medical advances in early detection and treatment of associated injuries have improved the overall outcome in TBI. Severely injured victims transported rapidly by helicopter or ambulance have better outcomes compared to those who cannot be transported quickly.

When possible, persons with severe head injuries are taken to a hospital with a dedicated trauma center. Such centers have specialized staff and equipment, and their patients have better outcomes compared to those taken to general hospitals. The initial evaluation measures vital signs such as temperature, blood pressure, pulse, and breathing rate, while the neurological examination assesses reflexes, level of consciousness, ability to move the limbs, and pupil size, symmetry, and response to light.

Neurological features are standardized using the Glasgow Coma Scale (GCS), a test scored from 1 to 15 points. Each of three measures (eye opening, best verbal response, and best motor response) is scored separately, and the combined score helps determine the severity of TBI. A total score of 3–8 reflects a

severe TBI, 9–12 a moderate TBI, and 13–15 a mild TBI. The lowest possible score, 3, usually indicates a fatal injury. There is a modified version of the GCS for use with infants and children.

Tests

Definitive diagnosis of a TBI is provided by imaging studies. Sophisticated imaging tests can help differentiate the variety of unconscious states associated with TBI and can help determine their anatomical basis. Until neck fractures or spinal instability have been ruled out with skull and neck x rays, or with head and neck computed tomography (CT) scans for more severe injuries, the patient should remain immobilized in a neck and back restraint.

By constructing a series of cross-sectional slices, or x-ray images through the head and brain, CT scans can diagnose bone fractures, bleeding, hematomas, contusions, swelling of brain tissue, and blockage of the ventricular system that circulates cerebrospinal fluid around the brain. In later stages after the initial injury, scans may also show shrinkage of brain volume in areas where neurons have died.

Using magnetic fields to detect subtle changes in brain tissue related to differences in water content, **magnetic resonance imaging** (MRI) scans show more detail than x rays or CT. However, MRI takes more time than CT and is not as readily available, making it less suited for routine emergency imaging.

For patients with seizures or for those with more subtle episodic symptoms thought to be seizures, an electroencephalogram (EEG) may reveal abnormalities in the electrical activity of the brain, or brain waves. Other diagnostic techniques that may be helpful include cerebral **angiography**, transcranial Doppler **ultrasound**, and **single photon emission computed tomography** (SPECT).

Treatment

Although no specific treatment may be needed for a mild head injury, it is crucial to watch the person closely for any developing symptoms over the next 24 hours. Over-the-counter pain relievers like **acetaminophen** or ibuprofen may be used for mild headache. **Aspirin** should not be given because it can increase the risk of bleeding.

If the person is sleeping, he or she should be awakened every two to three hours to determine alertness and orientation to name, time, and place. Immediate medical help is needed if the person becomes unusually drowsy or disoriented, develops a severe headache or stiff neck, vomits, loses consciousness, or behaves abnormally.

Emergency care and surgery

Treatment for moderate or severe TBI should begin as soon as possible by calling 911 and beginning emergency care until the EMT team arrives. This care includes stabilizing the head and neck by placing the hands on both sides of the person's head to keep the head in line with the spine and prevent movement, which could worsen spinal cord injury. Bleeding should be controlled by firmly pressing a clean cloth over the wound. If a skull fracture is suspected, it should be covered with sterile gauze dressing without applying pressure. If the person is vomiting, the head, neck, and body should be rolled to the side as one unit to prevent **choking** without further injuring the spine.

Although the initial brain damage caused by trauma is often irreversible, the goal is to stabilize the patient and prevent further injury. To achieve these goals, the treatment team must insure adequate oxygen supply to the brain and the rest of the body, maintain blood flow to the brain, control blood pressure, stabilize the airway, assist in breathing or perform CPR if necessary, and treat associated injuries. Recent research has found that increasing the patient's caloric intake by 50% during the first two weeks after the TBI helps reduce inflammation and gives the brain the energy it needs to heal.

About half of severe head injuries require **neurosurgery** for hematomas or contusions. Swelling of the injured brain may cause increased intracranial pressure (ICP) within the closed skull cavity. ICP can be measured with an intraventricular probe or catheter inserted through the skull into the fluid-filled chambers (ventricles) within the brain. Placement of the ICP catheter is usually guided by CT scan. If ICP is elevated, ventriculostomy may be needed. This procedure drains cerebrospinal fluid from the brain and reduces ICP. Drugs that may decrease ICP include mannitol and **barbiturates**.

Drugs

Although some patients need medication for psychiatric and physical problems resulting from the TBI, prescribing drugs may be problematic, because TBI patients are more sensitive to side effects.

Rehabilitation

Both in the immediate and later stages of TBI, **rehabilitation** is vital to optimal recovery of the patient's ability to function at home and in society. Rehabilitation is a highly individualized process and is based on each patient's specific strengths and abilities.

Problems with orientation and thinking and communication problems should be addressed early, often during the hospital stay. The focus is typically on improving alertness, attention, orientation, speech understanding, and swallowing problems.

As the patient improves, rehabilitation should be modified accordingly. **Physical therapy**, **occupational therapy**, speech or language therapy, physiatry (physical medicine), psychology or psychiatry, and social support should all play a role in TBI rehabilitation. Appropriate settings for rehabilitation may include the patient's home, the hospital outpatient department, inpatient rehabilitation centers, comprehensive day programs, supportive-living programs, independent-living centers, and school-based programs. Families should become involved in rehabilitation, in modifying the home environment if needed, and in **psychotherapy** or counseling as indicated.

Prognosis

The prognosis of TBIs is highly individualized and varies with their severity and cause: 91% of TBIs

WWW.BOOKBAZ.IR

caused by firearms (two-thirds of which may represent **suicide** attempts) are fatal, compared with only 11% of TBIs from falls.

Following TBI, patients may be at increased risk of such other long-term problems as Parkinson's disease, Alzheimer's disease, "punch-drunk" syndrome (**dementia** pugilistica), and post-traumatic dementia. Some patients may have difficulty returning to work following TBI, as well as problems with school, driving, sports, housework, and social relationships.

Mental health issues

Mental disorders and behavioral problems are common sequelae of TBIs. The most common are depression and behavioral problems. A report published in the August 2011 edition of the journal *Schizophrenia Bulletin* found that persons with TBIs may also be at risk for developing **schizophrenia**, being 1.6 times more likely to develop the disorder than persons in the general population. A major reason for the development of mental disorders after TBI is that the parts of the brain most susceptible to traumatic injury—the frontal and temporal lobes—are the portions of the brain that are responsible for executive functions (judgment, reasoning, decision making, evaluating a situation, processing information, etc.). These portions of the brain contain such structures as the hippocampus, which helps to form long-term memory; Broca's and Wernicke's areas, which govern speech; and the amygdala, which processes emotions and is also responsible for memory consolidation. Thus, damage to the frontal and temporal lobes can have long-term behavioral and psychiatric consequences.

DEPRESSION. Depression is a common mood disorder that affects TBI patients; about half of all persons with a TBI will be diagnosed with major depression within a year after injury. Many TBI patients with depression also have concurrent **anxiety disorders**. Depression following a TBI usually results from a combination of factors that include physical changes in the brain after injury; emotional reactions to such changes as job or role loss, short- or long-term disability, loss of self-sufficiency and other losses; a personal or family history of depression; and genetic susceptibility to **mood disorders**.

Depression following a TBI is treated in the same way as depression in the general population, most often with a combination of antidepressant medications and cognitive behavioral or **group therapy**. Some patients with depression following a TBI report being helped by **yoga**, other gentle forms of **exercise**, **acupuncture**, and **biofeedback**.

Behavioral problems

Behavioral problems are another common sequela of a TBI. The problematic behaviors most frequently encountered in TBI patients are agitation, impulsive behaviors, loss of inhibition, and loss of motivation. Aggressive outbursts toward others, cursing, yelling, inappropriate sexual behaviors, self-injury, property destruction, and noncompliance with treatment can all hinder relationships with family members, return to work, and reintegration within the larger community. Assessment of the frequency and severity of behavioral problems is an important part of evaluation. For example, occasional temper tantrums in the home are one matter, but aggression may evolve to violence, placing friends and family in dangerous situations. Although some problem behaviors may not be physically dangerous to others, having them repeated literally hundreds of times a day can damage family relationships as well as the possibility of employment.

One way to understand behavioral problems in patients with TBIs is that they result from a combination of changes in the functioning of the patient's brain and negative feedback from the surrounding environment. The affected person may not be able to detect and respond to the social cues and feedback that remind most people of the limits of acceptable behavior. In return, healthcare workers as well as family members may respond to the problem behaviors by reprimanding or punishing the individual, which often makes the behavioral problems worse.

An additional complication in addressing problem behaviors in patients with TBIs is that there is no consensus regarding the best therapeutic approach. There are many different schools of psychiatry and psychotherapy, and treatment recommendations based on one theory of human behavior may vary considerably from recommendations based on a different theory. No two TBIs are identical, nor are the patients affected by them. Some general recommendations for treating behavioral problems are as follows:

- The individual should have a complete neurological examination and imaging studies to determine as precisely as possible which parts of the brain have been injured, along with the severity of the damage.
- Mild behavioral problems can often be managed in community settings or outpatient clinics with a combination of behavioral therapy and medications. The patient should be involved in the design of the treatment plan as much as possible.
- Some behavioral problems can also be managed by changing the patient's environment to minimize confusion and frustration.

- Severe behavioral problems often require inpatient treatment. The patient's family or friends, however, should make sure that the facility is staffed by physicians, psychologists, speech pathologists, and other therapists with extensive training and specific expertise in treating behavior problems resulting from TBIs. Other concerns include the safety of the facility (to prevent self-injury) and its security (to prevent the patient's wandering away).

Cognitive dysfunction

Cognition refers to a set of mental functions that include attention, memory, language, problem solving, logic, and decision making. Memory itself is a complex set of active storage processing that encodes information rather than just passively storing it. Cognitive skills assist memory by identifying what is important to remember in a given situation and by rearranging what is stored in memory when a person learns new information. In many cases, what appears to be **memory loss** in patients with TBIs is really a consequence of other cognitive deficits, such as difficulty concentrating or damage to vision and other forms of sensory perception.

In general, cognitive deficits are most noticeable immediately after the person emerges from coma (if they have lost consciousness). Although there are exceptions, a common rule of thumb is that recovery of cognition is most rapid in the first 6–12 months after injury, and proceeds at a slower pace for the next 1–3 years. With regard to assessment of the person's cognitive abilities, most doctors recommend waiting until the person's condition has stabilized sufficiently to allow them to participate in a meaningful assessment.

Cognitive assessments serve several purposes, including identification of specific cognitive abilities and deficits, evaluating treatment outcomes, monitoring the patient's recovery, designing a treatment program, assessing the person's educational and occupational future, and documenting symptoms for legal purposes, particularly for decisions about the person's competency or applying for Medicaid or Social Security benefits. The cognitive assessment is usually repeated, as it is not unusual for new symptoms to appear as previous symptoms resolve. An example would be the appearance of difficulties with impulse control after the patient's initial loss of interest in activity has disappeared.

There are different treatment strategies for different cognitive deficits, although most involve long-term therapy; recovery of cognitive skills is a slow process that usually takes years, not months. Assistive technologies, such as wristwatches that beep to remind the person of a task or computer software that helps with organizing and managing complex information, are useful to many patients. Those with low mental stamina or difficulties with concentration may be helped by fatigue management strategies or by medications that have been shown to improve alertness and the ability to focus attention. With regard to impairment-specific treatments, speech-language therapy and treatment for loss of visual/spatial coordination have yielded better results than memory training strategies. Deficits in executive skills have been effectively treated by a combination of individualized psychotherapy and coaching in real-life situations, including the workplace.

Veterans' issues

TBI has been described as the "signature" injury of the conflicts in Iraq and Afghanistan; the rate of such injuries is higher in veterans of Iraq and Afghanistan compared to Vietnam veterans (12%). Veterans' advocates believe that between 10% and 20% of Iraq veterans (150,000–300,000 men and women) have some level of TBI. Among wounded troops, the rate of TBI is as high as 33%. The major causes of TBIs in recent veterans are blasts, motor vehicle accidents, and gunshot **wounds**. Unfortunately, TBI is underdiagnosed and undertreated in military personnel. In 2008, the U.S. Department of Defense awarded a four-year grant to the Brain Trauma Foundation (BTF) to develop an eye-tracking device that can be used in the field to instantly determine if a soldier or airman has suffered any brain damage as a result of blast injury or another type of head injury.

Because many veterans with TBIs have coexisting PTSD or substance abuse disorders, they typically take longer than civilians to recover from these head injuries. Women veterans with TBIs are more likely than male veterans to be diagnosed with concurrent depression. Veterans with TBIs are also almost twice as likely to attempt suicide as veterans who did not sustain such injuries. Treatment for TBIs in veterans is similar to that for civilians, with rehabilitation programs that address cognitive retraining, psychosocial adjustment, communication and leisure skills, and vocational issues. The U.S. Veterans Administration (VA) maintains 4 polytrauma rehabilitation centers and 21 polytrauma network sites for veterans with the most severe TBIs.

Prevention

Not all accidents or other causes of TBIs can be prevented. People can, however, lower their risk by taking the following safety measures:

WWW.BOOKBAZ.IR

- Athletes should wear protective headgear for such sports as mountain climbing, martial arts, football, baseball, bicycling, motorcycling, rollerblading, and skateboarding. They should make sure their helmets and other protective gear are properly fitted. Coaches should insist that players are taught the rules of safe play and that they follow them. Players should report all head injuries to the team doctor even if they seem minor at the time.
- Adults and children should be careful when diving in shallow water, particularly in bodies of water with rocky shores and bottoms.
- Drivers and passengers should always wear seat belts when traveling in a motor vehicle, and people should never drive when under the influence of alcohol or other drugs.
- People in occupations requiring hardhats should wear them at all times, particularly in mining and construction work. Even a small object dropped from the upper floors of a building can cause a serious head injury.
- Elderly persons or parents of small children should check their house or apartment for loose rugs, poor lighting, slippery floors, and other problems that increase the risk of falls, which are a common cause of TBIs in the very old and very young.

Traveler's diarrhea

Definition

The occurrence of multiple loose bowel movements in someone traveling to an area outside their usual surroundings (usually from temperate industrialized regions to tropical areas), is known as travelers' **diarrhea** (TD). The cause is almost always due to a bacterial or viral infection acquired through ingesting contaminated food or water.

Description

It is estimated that anywhere from 20–50% of the 12–20 million travelers going from temperate industrialized countries to the tropics will develop TD. Most of these episodes are of short duration. Nevertheless, about 40% of those affected will need to rearrange their schedule, and 20% will be ill enough to remain in bed for some days.

The chance of winding up with TD is directly related to the area one is visiting: Only about 8% of individuals visiting an industrialized country are affected, whereas at least half of those traveling to non-industrialized regions become ill. It is also clearly related to the number of potentially contaminated foods or beverages consumed. Attention to recommended guidelines regarding food safety and sanitation can greatly decrease the risk of infection.

Causes and symptoms

Bacterial infections are the most common cause of the illness. Viruses and occasional parasites also can be the cause.

WWW.BOOKBAZ.IR

Among bacteria, toxin-producing types of *E. coli* (called enterotoxigenic) account for approximately 40–60% of cases, with *Campylobacter* and *Shigella* each reported in at least 10% of cases. *Campylobacter* can be especially troublesome during cooler seasons of the year. More than one organism can be found in 15–30% of cases, while none is identified in up to 40% of cases worldwide.

Rotaviruses and a parvovirus called Norwalk agent also are responsible for TD. *Giardia* is probably the most common parasite identified, though amoebas (*Entamoeba histolytica*), *Cryptosporidium*, and *Cyclospora* have been increasingly noted as the causes of TD.

Younger age groups, particularly students, are at greatest risk, probably because of where and what they eat. Individuals more than 55 years of age, persons staying with relatives, or business travelers are at lower risk. Foods with the highest chance of transmitting disease are uncooked vegetables, unpeeled fruits, meat, and seafood. Tap water and even ice can be dangerous unless one is sure of the source.

Symptoms usually start within a few days after arrival to a new destination, but can be delayed for as long as two weeks. Illness lasts an average of three to five days, but is sometimes longer. Cramping abdominal **pain**, lack of appetite, and diarrhea are the main complaints. **Fever** develops in about 50% and diarrhea turns bloody in about 10%. The presence of bloody bowel movements and fever usually indicates a more severe form of illness, which is often caused by *Shigella*. (Medications that decrease the motility or contractions of the intestine, such as loperamide [Imodium] or diphenoxylate [Lomotil], should not be used when fever or bleeding occur.)

Diarrhea varies from a few loose stools per day to 10 or more. **Dehydration** and changes in the normal blood pH (acid-base balance) are the main dangers associated with TD. Signs of dehydration may not be obvious, but increasing thirst, **dry mouth**, weakness or lightheadedness (particularly if worsening while standing), or a darkening/decrease in urination are suggestive. Severe dehydration and changes in the body's chemistry can lead to kidney failure and become life-threatening.

Another potential complication is toxic megacolon, in which the colon gradually stretches and its wall thins to the point where it can tear. The presence of a hole in the intestine leads to **peritonitis** and is fatal unless quickly recognized and treated.

Other complications related to TD can involve the nervous system, skin, blood, or kidneys.

Diagnosis

The occurrence of diarrhea in an individual while traveling is very suggestive of TD. Although there are other possible causes, these are less likely. In most instances, the specific organism responsible for the symptoms does not need to be identified, and the majority of patients need only rest and treatment to avoid potential complications.

When patients develop fever or bloody diarrhea, the illness is more serious and a specific diagnosis is needed. In those cases, or when symptoms last longer than expected, stool samples are obtained to identify the organism.

For this purpose, laboratories use freshly obtained stool samples either to try to grow (culture) the organism, or to identify it with high-powered microscopes (electron microscopy) or with the use of special tests or stains. These can show parasites such as *Giardia, Amoeba,* and *Cryptosporidium*. New techniques that involve identification of DNA (the characteristic material that controls reproduction and is unique for all individuals) of the various organisms, also may be used in some instances.

Treatment

The best treatment of TD is prevention. Once disease occurs, therapy is aimed at preventing or reducing dehydration, and using **antibiotics** when needed. Severe dehydration is unusual in patients with TD, but any fluid losses should be treated early with either fruit juices and clear fluids such as tea or broth, or with the recommended oral rehydration solutions (ORS) suggested by the World Health Organization (WHO). Persons traveling to known areas of infection should consult with their physician prior to departure and obtain appropriate instructions. For example, it may be advised to take along already-prepared packets of ORS designed for easy mixing, or commercial preparations (e.g., Pedialyte, Ceralyte, Ricelyte), or the healthcare professional may suggest a homemade solution.

Pepto-Bismol (bismuth subsalicylate preparation) is effective in treating TD. Bismuth subsalicylate preparation (some experts recommend 1 oz of liquid or two 262.5-mg tablets every 30 minutes for eight doses, and others suggest 2 oz or two tablets four times a day) has been shown to decrease the number of bowel movements and shorten the length of illness. People who have kidney problems, an **aspirin** allergy, **gout**, or are taking other medications should first consult their physician before starting this or any other therapy.

Patients should be aware that bismuth can turn bowel movements black in color.

A drug called rifamixin (Normix) for treating TD was approved by the U.S. Food and Drug Administration (FDA) in 2010. Medications designed to decrease intestinal motility and contractions such as loperamide (Imodium), diphenoxylate (Lomotil), or others are safest when used by those without fever or bloody bowel movements. The presence of either of these symptoms indicates a more severe form of **colitis**.

Antibiotics are usually not prescribed, because most cases of TD rapidly improve with minimal treatment. The exceptions are patients with especially severe symptoms (four or more stools per day or the onset of bloody diarrhea or fever), and those with compromised immune systems. Individuals with less severe attacks can be treated with either anti-motility medications or bismuth subsalicylate.

Choice of an antibiotic should ideally be tailored to the most likely organism and then adjusted according to results of stool cultures. Trimethoprim-sulfamethoxazole (Bactrim) or ciprofloxacin (Cipro) are the antibiotics most often prescribed, but others are also used. The type and duration of treatment continues to be revised, and it is extremely important that patients check with a physician prior to beginning treatment. In many instances, an antibiotic can be combined with an anti-motility agent to provide the quickest relief.

Prognosis

Up to 1% of patients with TD will become sick enough to require hospitalization, and 3% will continue to experience diarrhea for at least one month. The majority of patients rapidly recover with minimal therapy. Some will have symptoms for even longer. The small number who continues to have symptoms will need careful evaluation to rule out the many causes of chronic diarrhea (such as lactase deficiency, **irritable bowel syndrome**, parasites, etc.). It is unusual for diarrhea caused by bacteria to last more than two weeks; therefore, more prolonged diarrhea indicates a non-bacterial cause.

Prevention

The best means of prevention is avoiding foods, beverages, and food-handling practices that lead to infection with the organisms that cause TD. Drinking bottled water and using bottled water for brushing teeth, eating fruits that the traveler peels on his or her own, and eating well-cooked, hot foods can help prevent illness.

KEY TERMS

Oral Rehydration Solution (ORS)—A liquid preparation developed by the World Health Organization that can decrease fluid loss in persons with diarrhea. Originally developed to be prepared with materials available in the home, commercial preparations have recently come into use.

One effective means to prevent TD is liquid Pepto-Bismol, which has been shown to be very effective in reducing the incidence of TD. Two tablets four times a day is recommended, but use should not go beyond three weeks. Studies have also shown that rifaximin can also reduce the risk of TD.

Tremors

Definition

Tremor is an unintentional (involuntary), rhythmical alternating movement that may affect the muscles of any part of the body. Tremor is caused by the rapid alternating contraction and relaxation of muscles and is a common symptom of diseases of the nervous system (neurologic disease).

Description

Occasional tremor is felt by almost everyone, usually as a result of fear or excitement. However, uncontrollable tremor or shaking is a common symptom of disorders that destroy nerve tissue, such as Parkinson's disease or **multiple sclerosis**. Tremor may also occur after **stroke** or **head injury**. Other tremors appear without any underlying illness.

Causes and symptoms

Tremor may be a symptom of an underlying disease, and it may be caused by drugs. It may also exist as the only symptom (essential tremor).

Underlying disease

Some types of tremor are signs of an underlying condition. About a 1.5 million Americans have Parkinson's disease, a disease that destroys nerve cells. Severe shaking is the most apparent symptom of Parkinson's disease. This coarse tremor features four to five muscle movements per second. The shaking is evident at rest but declines or disappears during movement.

Other disorders that cause tremor are multiple sclerosis, Wilson's disease, **mercury poisoning**, thyrotoxicosis, and **liver encephalopathy**.

A tremor that gets worse during body movement is called an intention tremor. This type of tremor is a sign that something is amiss in the cerebellum, a region of the brain concerned chiefly with movement, balance and coordination.

Essential tremor

Many people have essential tremor, in which the tremor is the only symptom. This type of shaking affects 3–4 million Americans.

The cause of essential tremor is not known, although it is an inherited problem in more than half of all cases. The genetic condition has an autosomal dominant inheritance pattern, which means that any child of an affected parent will have a 50% chance of developing the condition.

Essential tremor most often appears when the hands are being used, whereas a person with Parkinson's disease will most often have a tremor while walking or while the hands are resting. People with essential tremor will usually have shaking head and hands, but the tremor may involve other parts of the body. The shaking often begins in the dominant hand and may spread to the other hand, interfering with eating and writing. Some people also develop a quavering voice.

Essential tremor affects men and women equally. The shaking often appears at about age 45, although the disorder may actually begin in adolescence or early adulthood. Essential tremor that begins very late in life is sometimes called senile tremor.

Drugs and tremor

Several different classes of drugs can cause tremor as a side effect. These drugs include amphetamines, **antidepressant drugs**, **antipsychotic drugs**, **caffeine**, and lithium. Tremor also may be a sign of withdrawal from alcohol or street drugs.

Diagnosis

Close attention to where and how the tremor appears can help provide a correct diagnosis of the cause of the shaking. The source of the tremor can be diagnosed when the underlying condition is found. Diagnostic techniques that make images of the brain, such as computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI), may help form a diagnosis of multiple sclerosis or other tremor caused by disorders of the central nervous system.

KEY TERMS

Computed tomography (CT) scan—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Essential tremor—An uncontrollable (involuntary) shaking of the hands, head, and face. Also called familial tremor because it is sometimes inherited; it can begin in the teens or in middle age. The exact cause is not known.

Fetal tissue transplantation—A method of treating Parkinson's and other neurological diseases by grafting brain cells from human fetuses onto the affected area of the human brain. Human adults cannot grow new brain cells but developing fetuses can. Grafting fetal tissue stimulates the growth of new brain cells in affected adult brains.

Intention tremor—A rhythmic purposeless shaking of the muscles that begins with purposeful (voluntary) movement. This tremor does not affect muscles that are resting.

Liver encephalopathy—A condition in which the brain is affected by a buildup of toxic substances that would normally be removed by the liver. The condition occurs when the liver is too severely damaged to cleanse the blood effectively.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Multiple sclerosis—A degenerative nervous system disorder in which the protective covering of the nerves in the brain are damaged, leading to tremor and paralysis.

Pallidotomy—A surgical procedure that destroys a small part of a tiny structure within the brain called the globus pallidus internus. This structure is part of the basal ganglia, a part of the brain involved in the control of willed (voluntary) movement of the muscles.

Parkinson's disease—A slowly progressive disease that destroys nerve cells. Parkinson's is characterized by shaking in resting muscles, a stooping posture, slurred speech, muscular stiffness, and weakness.

Thalamotomy—A surgical procedure that destroys part of a large oval area of gray matter within the brain that acts as a relay center for nerve impulses. The thalamus is an essential part of the nerve pathway that controls intentional movement. By destroying tissue at a particular spot on the thalamus, the surgeon can interrupt the nerve signals that cause tremor.

Thalamus—A large oval area of gray matter within the brain that relays nerve impulses from the basal ganglia to the cerebellum, both parts of the brain that control and regulate muscle movement.

Thyrotoxicosis—An excess of thyroid hormones in the blood, causing a variety of symptoms that include rapid heart beat, sweating, anxiety, and tremor.

Tremor control therapy—A method for controlling tremor by self-administered shocks to the part of the brain that controls intentional movement (thalamus). An electrode attached to an insulated lead wire is implanted in the brain; the battery power source is implanted under the skin of the chest, and an extension wire is tunneled under the skin to connect the battery to the lead. The patient turns on the power source to deliver the electrical impulse and interrupt the tremor.

Wilson's disease—An inborn defect of copper metabolism in which free copper may be deposited in a variety of areas of the body. Deposits in the brain can cause tremor and other symptoms of Parkinson's disease.

Blood tests can rule out such metabolic causes as thyroid disease. A family history can help determine whether the tremor is inherited.

Treatment

Neither tremor nor most of its underlying causes can be cured. Most people with essential tremor respond to drug treatment, which may include propranolol, primidone, or a benzodiazepine. People with Parkinson's disease may respond to levodopa or other **antiparkinson drugs**.

Research has shown that about 70% of patients treated with botulinum toxin A (Botox) have some improvement in tremor of the head, hand, and voice. Botulinum is derived from the bacterium *Clostridium botulinum*. This bacterium causes **botulism**, a form of **food poisoning**. It is poisonous because it weakens muscles. A very weak solution of the toxin is used in

WWW.BOOKBAZ.IR

cases of tremor and **paralysis** to force the muscles to relax. However, some patients experience unpleasant side effects with this drug and cannot tolerate effective doses. For other patients, the drug becomes less effective over time. About half of patients do not get any relief of tremor from medications.

Tremor control therapy

Tremor control therapy is a type of treatment using mild electrical pulses to stimulate the brain. These pulses block the brain signals that trigger tremor. In this technique, the surgeon implants an electrode into a large oval area of gray matter within the brain that acts as a relay center for nerve impulses and is involved in generating movement (thalamus). The electrode is attached to an insulated wire that runs through the brain and exits the skull where it is attached to an extension wire. The extension is connected to a generator similar to a heart pacemaker. The generator is implanted under the skin in the chest, and the extension is tunneled under the skin from the skull to the generator. The patient can control his or her tremor by turning the generator on with a hand-held magnet to deliver an electronic pulse to the brain.

Some patients experience complete relief with this technique, but for others it is of no benefit at all. About 5% of patients experience complications from the surgical procedure, including bleeding in the brain. The procedure causes some discomfort, because patients must be awake while the implant is placed. Batteries must be replaced by surgical procedure every three to five years.

Other surgical treatments

A patient with extremely disabling tremor may find relief with a surgical technique called thalamotomy, in which the surgeon destroys part of the thalamus. However, the procedure is complicated by numbness, balance problems, or speech problems in a significant number of cases.

Pallidotomy is another type of surgical procedure sometimes used to decrease tremors from Parkinson's disease. In this technique, the surgeon destroys part of a small structure within the brain called the globus pallidus internus. The globus is part of the basal ganglia, another part of the brain that helps control movement. This surgical technique also carries the risk of disabling permanent side effects.

Fetal tissue transplantation (also called a nigral implant) is a controversial experimental method to treat Parkinson's disease symptoms. This method implants fetal brain tissue into the patient's brain to replace malfunctioning nerves. Unresolved issues include how to harvest the fetal tissue and the moral implications behind using such tissue, the danger of tissue rejection, and how much tissue may be required. Although initial studies using this technique looked promising, there has been difficulty in consistently reproducing positive results.

Small amounts of alcohol may temporarily (sometimes dramatically) ease the shaking. Some experts recommend a small amount of alcohol (especially before dinner). The possible benefits, of course, must be weighed against the risks of alcohol abuse.

Prognosis

Essential tremor and the tremor caused by neurologic disease (including Parkinson's disease) slowly get worse and can interfere with a person's daily life. While the condition is not life-threatening, it can severely disrupt a person's everyday experiences.

Prevention

Essential tremor and tremor caused by a disease of the central nervous system cannot be prevented. Avoiding use of stimulant drugs such as caffeine and amphetamines can prevent tremor that occurs as a side effect of drug use.

Trench fever

Definition

Trench **fever** is a bacterial infection that causes repeated cycles of high fever.

Description

The term trench fever refers to the crowded conditions in which troops fought in during World War I and World War II. Because the causative bacteria are passed among humans through contact with body lice, overcrowding, and conditions that interfere with good hygiene (including regular washing of clothing) soldiers were predisposed to this disease. Homeless people in the United States are sometimes diagnosed with this illness. The bacteria are sometimes passed through the bite of an infected tick. This can cause the illness in people who participate in outdoor activity and encounter ticks in that particular area.

Causes and symptoms

Two different bacteria can cause trench fever: *Bartonella quintana* and *Bartonella henselae*. *B. quintana* is carried by body lice; *B. henselae* is carried by ticks.

Infection with *B. quintana* occurs when an infected louse defecates while feeding on a human. When the person scratches, the feces (which are full of bacteria) are rubbed into the tiny wound. Infection with *B. henselae* occurs when an infected tick bites a human, passing the bacteria along through the tiny bite wound.

Symptoms of trench fever begin about 2 weeks to a month after exposure to the bacteria. Sudden fever, loss of energy, **dizziness**, **headache**, weight loss, skin rash, severe muscle and bone **pain** can occur. Pain is particularly severe in the shins, leading to the nickname "shin bone fever." The fever can reach 105°F (40.5°C) and stays high for 5–6 days at a time. The temperature then drops, and stays down for several days, usually recurring in five- to six-day cycles. An individual may experience as many as eight cycles of fever with the illness.

Diagnosis

Diagnosis is usually made on the basis of the patient's symptoms, and on knowledge of the conditions in which the patient lives. A blood sample can be drawn and bacteria in the sample are allowed to grow. Identification is made by looking at the number of bacteria that may be present on a glass slide seen under the lens of a microscope. However, this technique can take up to four weeks, because this type of bacterium grows very slowly. By this time, the practitioner has often decided to treat the patient anyway.

Treatment

Erythromycin and azithromycin are both used to treat trench fever. Four weeks of treatment are usually necessary. Inadequate treatment often results in a relapse. Relapses have been reported to occur as long as 10 years after the first episode.

Prognosis

Prognosis for patients with trench fever is excellent. Recovery may take a couple of months. Without treatment, there is always a risk of recurrence, even years after the original illness.

Prevention

Prevention involves good hygiene and decent living conditions. When this is impossible, insecticide dusting powders are available to apply to clothing. Avoidance of areas known to harbor ticks or the use of insect repellents is necessary to avoid the type of infection passed by ticks.

Trichinosis

Definition

Trichinosis is a disease caused by a roundworm (nematode) called *Trichinella spiralis*. An individual worm of this species is called a trichina, from the Greek word meaning "hairlike." Trichinae can be readily avoided by proper handling and cooking of certain meats, particularly pork products.

Description

The life cycle of *T. spiralis* includes several different stages. The adult trichina lives in the intestinal lining of such meat-eating animals as swine, bears, walrus, and rodents. After mating, the male worm dies while the female goes on to produce the offspring.

WWW.BOOKBAZ.IR

Roundworms have a stage of development called the embryonic stage, which in many species occurs after birth. In trichinae, however, this embryonic stage occurs within the uterus of the female, so the offspring that are ultimately discharged into the host's intestinal lining are in the larval second stage of life. These larvae—about 1,500 from each female worm—travel through the circulatory system to the heart, then through the blood vessels leading to striated muscle (the muscle of the skeletal system and the heart). Most larvae that cannot find suitable locations in striated muscle will die.

Those larvae that reach striated muscle will grow to a length of about 1 mm, coil themselves, and enclose themselves within a protective wall called a cyst. This process is referred to as encysting. The worms in the cysts can live up to ten years in this form.

A pig that has been infected with *T. spiralis*, then, has thousands of cysts lying dormant within its muscles– the very muscles that humans look forward to consuming in the form of pork chops, ham, barbecued ribs, etc. When humans sit down to a delicious meal of undercooked, trichina-infected pig dinner, they are ingesting *T. spiralis* cysts. The cyst walls are broken down by the usual process of food digestion in the stomach, allowing the larvae to escape into the new host's intestines. There the larvae mature to become adult worms, capable of producing a new crop of larvae. When these new larvae hatch, they begin their migration throughout the human host's bloodstream to his or her muscles, where they live for a short while before encysting.

Causes and symptoms

Human hosts who eat meat infested with trichinae may experience symptoms in varying degrees. If the meat ingested has only a few cysts, then the human host's load of parasites (worm burden) is said to be relatively small, and symptoms will be moderate. In fact, many trichinosis infections are subclinical, which means that the symptoms are so mild that the infection remains undiagnosed. In a host with a greater worm burden, the initial symptoms will be caused by the presence of the adult worms in the intestine. These symptoms usually include **fever**, **diarrhea**, abdominal **pain**, and perhaps **vomiting**. The symptoms begin about one to two days after eating the contaminated meat, and may last for a week or so.

When the larvae begin their migration through the blood vessels, the host will begin to experience symptoms that affect the whole body (systemic symptoms), such as fever; swelling of the face and the area around the eyes; rash; bleeding into the nail beds, retina, and whites of the eyes; and **cough**. In very severe cases of trichinosis, inflammation of the heart muscle (**myocarditis**), lungs (pneumonitis), or brain (encephalitis) may occur. These symptoms can lead to the few deaths caused by trichinosis.

The larvae begin to burrow into the host's muscles and form cysts within two to three weeks of the initial infection. This encysting produces signs of muscle inflammation (**myositis**) including swelling of the affected muscle groups, pain, and weakness. The most frequently affected muscles are the muscles outside the eye (extraocular muscles) that control eye movements; the muscles of the jaw, neck, and upper arm (biceps muscle); the muscles of the lower back (lumbar region); and the diaphragm, which is the muscle that separates the abdominal and chest cavities and aids in breathing.

The symptoms of trichinosis are at their most severe at about three weeks after infection, and decrease very slowly in their severity. Recovery is extremely gradual, and symptoms may last for as long as three months. **Fatigue** and muscle pain (myalgia) may take several more months to subside.

Diagnosis

An initial diagnosis of trichinosis relies heavily on the presence of its classic symptoms—swelling around the eyes, muscle inflammation, fever, and high levels of a certain type of white blood cell (eosinophils)– coupled with the patient's history. If the patient reports having eaten undercooked meat from an animal known to be a potential carrier of trichinosis, the doctor may order a muscle biopsy to confirm the diagnosis. By the third or fourth week of infection, muscle biopsies usually indicate the presence of larvae. Stool tests rarely reveal adult worms, although larvae can sometimes be found in blood or duodenal washings after the second week of infection. The blood test that is the most specific for trichinosis is the bentonite flocculation (BF) test.

T. spiralis can infect a number of different animal species used for food. The most common food culprit in the United States has been pork sausage, while outbreaks in Europe have been caused by wild boar and horse meat. Outbreaks of trichinosis in Asia and Africa have been traced to dog meat, and outbreaks in Northern Canada have resulted from consumption of walrus and bear meat.

KEY TERMS

Anthelminthic—A type of medication that is given to destroy or eliminate parasitic worms.

Cyst—In the life cycle of the round worm, a protective, walled-off capsule in which the larvae lie dormant.

Embryonic—In the life cycle of the round worm, a very early life stage occurring within the uterus of the female round worm.

Host—The animal within which a parasite lives, and from which the parasite receives its nutrition.

Inflammation—A reaction within the body to an invader (virus, bacteria, fungus, worm, etc.) or to tissue injury. The classic signs of inflammation include redness, heat, pain, and loss of function.

Larva—In the life cycle of the round worm, the second stage of life, sometimes considered the adolescent stage.

Nematode—A type of roundworm with a long, unsegmented body, usually parasitic on animals or plants.

Striated muscle—Also known as striped muscle; it includes muscles of the skeletal system and of the heart.

Trichina—An individual example of *Trichinella spiralis*.

Treatment

Supportive care

Treatment of trichinosis is primarily aimed at decreasing the severity of the symptoms. Symptomatic relief includes bed rest and medications to relieve fever and muscle pain. The medications most commonly given are **aspirin** and **nonsteroidal anti-inflammatory drugs** (NSAIDs). **Steroids** such as prednisone (Deltasone, Meticorten) are reserved for the most severe cases of muscle inflammation, or for complicated cases that include myocarditis.

Anthelminthic medications

In addition to medications for pain relief, trichinosis can be treated with drugs that are called anti-worm medications or anthelminthics. Two related anti-worm medications, mebendazole (Vermox) and thiabendazole (Mintezol), have been reported to be effective against intestinal larvae, but not against larvae encysted in the muscles. In particular, thiabendazole has worked best when given to patients who knew within 24 hours that they had eaten infested meat. Thiabendazole has, however, anti-inflammatory properties that can relieve some of the pain during the muscle stage of trichinosis.

Prognosis

The prognosis for recovery from trichinosis is generally good. Most people with the disease are unaware that they have even been infected. It is estimated that between 150,000 and 300,00 people in the United States become infected yearly, so that at any given time, 1.5 million people have *T. spiralis* infections. Most of these people have such light cases that trichinosis is never identified. Worm burden is measured in larvae per gram of muscle tissue; people with 10 or fewer larvae per gram of muscle tissue usually have no significant symptoms. When the number climbs to 100 larvae per gram of muscle tissue, the symptoms become noticeable. People with over 1,000 larvae per gram of muscle tissue are usually extremely ill, and often die. The mortality rate of trichinosis is about 1%.

Prevention

Prevention of trichinosis is relatively simple. Swine should be fed only grain or cooked garbage because uncooked garbage may contain contaminated pork scraps. Meat from animals prone to trichinosis infection should be cooked or smoked thoroughly until it is no longer pink. Freezing meat at an adequately low temperature (5°F [–15°C] for three weeks) can kill most encysted larvae, except for species that infect such arctic mammals as walrus or bear.

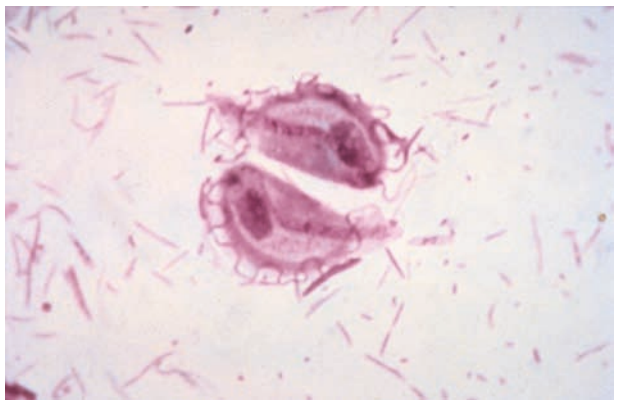
Trichomonas vaginalis infection *see* **Trichomoniasis**

Trichomoniasis

Definition

Trichomoniasis refers to an infection of the genital and urinary tract. It is the most common sexually transmitted disease, affecting about 120 million women worldwide each year.

WWW.BOOKBAZ.IR



A close-up image of *Trichomonas vaginalis*, the parasite that causes vaginitis in humans. *(Custom Medical Stock Photo, Inc.)*

Description

Trichomoniasis is caused by a protozoan (the smallest, single-celled members of the animal kingdom). *Trichomonas vaginalis* is passed almost 100% of the time through sexual contact. Trichomoniasis is primarily an infection of women's vaginal and urinary tracts. A woman is most susceptible to infection just after having completed her menstrual period. Men may carry the organism unknowingly, since infection in men may cause mild or no symptoms.

Causes and symptoms

Because trichomoniasis is a sexually transmitted disease, it occurs more often in individuals who have multiple sexual partners. The protozoan is passed to an individual by contact within the body fluids of an infected sexual partner. It often occurs simultaneously with other sexually transmitted diseases, especially **gonorrhea**.

In women, the symptoms of trichomoniasis include an unpleasant vaginal odor, and a heavy, frothy, yellow discharge from the vagina. The genital area (vulva) is often very itchy, and there is frequently **pain** with urination or with sexual intercourse. The labia (lips) of the vagina, the vagina itself, and the cervix (the narrowed, lowest segment of the uterus which extends into the upper part of the vagina) will be bright red and irritated.

In men, there are usually no symptoms at all. Occasionally, a man will notice a small amount of yellowish discharge from his penis, usually first thing in the morning. There may be some inflammation of the urethra, or **urethritis**, which produces mild discomfort while urinating.

The use of **antibiotics** is a contributing factor to recurrent trichomoniasis in some women because antibiotics affect the balance of bacteria in the vagina, allowing such organisms as *T. vaginalis* to multiply more rapidly.

Diagnosis

Diagnosis is easily made by taking a sample of the discharge from the women's vagina, or from the opening of the man's penis. The sample is put on a slide, and viewed under a microscope. The protozoa, which are able to move about, are easily viewed.

Trichomoniasis tends to be underdiagnosed in men because of the relative mildness of symptoms in men and insufficiently sensitive diagnostic tests. The recent introduction of DNA amplification, however, indicates that the incidence of trichomoniasis in men is much higher than was previously thought.

Treatment

The usual treatment is a single large dose of metronidazole, or split doses over the course of a week. Sexual partners of an infected individual must all be treated, to prevent the infection being passed back and forth.

Women who are taking antibiotics for other illnesses should speak to their healthcare provider about the possibile effects of the medication(s) on the balance of organisms in their vagina.

As of 2014, the number of cases of metronidazole-resistant trichomoniasis appears to be increasing, with an estimated 4–5% of all cases being deemed resistant. Some success has been reported with the broad-spectrum anti-parasitic drug nitazoxanide, but further research needs to be done. A group of researchers in Thailand is currently investigating the effectiveness of a group of drugs known as bisquaternary quinolinium salt compounds in treating trichomoniasis.

Alternatives

Cure of trichomoniasis may be difficult to achieve with alternative treatments. Some practitioners suggest eliminating sweets and carbohydrates from the diet and supplementing with **antioxidants**, including **vitamins** A, C, and E, and zinc. Naturopaths may recommend treatment with two douches (a wash used inside the vagina), alternating one in the morning and one at bedtime. One douche contains the herbs calendula (*Calendula officinalis*), goldenseal (*Hydrastis canadensis*), and **echinacea** (*Echinacea* spp.); the other douche contains plain yogurt. The herbal douche helps to kill the protozoa, while the yogurt

reestablishes healthy flora in the vagina. Another herbal remedy that is sometimes used is tea tree oil. Acidifying the vagina by douching with boric acid or vinegar may also be useful.

Prognosis

Prognosis is excellent with appropriate treatment of the patient and all sexual partners. Without treatment, the infection can smolder on for a very long time, and can be passed to all sexual partners.

Prevention

All sexually transmitted diseases can be prevented by using adequate protection during sexual intercourse. Effective forms of protection include male and female **condoms**.

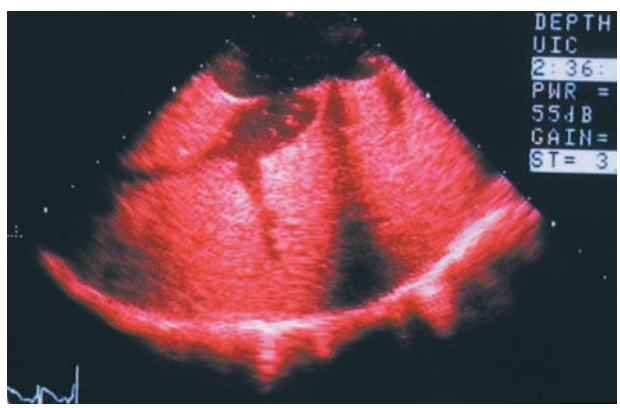
Tricuspid valve insufficiency

Definition

Tricuspid valve insufficiency occurs when a tricuspid valve does not close tightly enough to prevent leakage. This condition is also called tricuspid valve regurgitation and tricuspid incompetence.

Description

The tricuspid valve is located between the right atrium and the right ventricle of the heart. When the



This echocardiogram of the heart shows tricuspid valve insufficiency. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

right ventricle contracts, it is supposed to pump blood forward into the lungs. If the tricuspid valve does not close tightly, some of that blood leaks back into the right atrium. When the atrium receives its usual quantity of blood from veins leading to the heart, plus the leaking blood, the pressure inside the atrium increases. This higher pressure creates resistance to the flow of blood in the veins that enter the atrium from the body. In addition, this increase in pressure causes the right atrium to enlarge over time. Congestion from fluid buildup occurs, particularly in the liver and legs.

Causes and symptoms

If a person has serious lung disease or a narrowing of the pulmonary valve, the right ventricle must pump harder to force the blood through the pulmonary valve. In order to pump harder, the right ventricle enlarges and the valve opening stretches, causing the valve to leak.

Tricuspid valve insufficiency usually produces such vague symptoms as general weakness and **fatigue**. As the conditions worsens, a person experiences **pain** in the upper right part of the abdomen, caused by a congested and enlarged liver. The legs may also swell (**edema**).

An enlarged right atrium can cause **atrial fibrillation** (the atria flutters, rather than pumping in a regular rhythm) and severe tricuspid regurgitation of blood, which can eventually lead to **congestive heart failure**.

Diagnosis

A leaky valve can be heard with a stethoscope; the sound is called a heart murmur. Additional support for diagnosing tricuspid valve insufficiency comes from a medical history, physical exam, and chest x ray. Further testing with **echocardiography**, to show an image of the leakage and its severity, is the most helpful diagnostic test for this condition.

Treatment

Tricuspid valve insufficiency itself usually does not require treatment, since a tiny leakage occurs in most normal people. In certain cases, however, if there is underlying pulmonary valve disease or lung disease, those conditions should be treated.

If irregular heart rhythms or **heart failure** are present, they are usually treated independently of the valve insufficiency.

Since a person with known tricuspid valve insufficiency is at risk for infections of the heart, **antibiotics** should be taken before and after oral or dental surgery, or urologic procedures.

KEY TERMS

Atrial fibrillation—A rapid, uncoordinated quivering of the upper chamber of the heart.

Atrium—The upper chamber of the heart.

Pulmonary valve—The valve at the opening from the right ventricle to the artery that leads to the lungs.

Prognosis

Tricuspid valve insufficiency is not usually considered to be serious. If it is the result of other cardiopulmonary disease, the extent of those conditions effect the prognosis.

Prevention

In general, tricuspid valve insufficiency cannot be prevented.

Tricuspid valve stenosis

Definition

Tricuspid valve stenosis is a narrowing or stiffening of the opening in the valve. This stenosis causes increased resistance to blood flow through the valve.

Description

The tricuspid valve is located between the right atrium and the right ventricle of the heart. It is the largest of the four valves in the heart. When the tricuspid valve is narrowed or stiffened, it decreases the amount of blood that can flow through it. This decrease raises the pressure in the right atrium and causes the atrium to enlarge. It also causes the right ventricle to shrink, and lowers the cardiac output.

KEY TERMS

Rheumatic fever—An inflammatory illness that can follow strep throat, and could cause heart damage.

Causes and symptoms

Tricuspid valve stenosis is most often the result of **rheumatic fever**. On rare occasions, it is caused by a tumor or disease of the connective tissue. The rarest cause is a birth defect.

A person with tricuspid valve stenosis may experience generalized weakness and **fatigue**. Many people have **palpitations** and can feel fluttering in their neck. Over time, there may be **pain** in the upper right abdomen, due to increased congestion and enlargement of the liver.

Diagnosis

The noise produced by blood trying to flow through a stenotic valve can be heard with a stethoscope, and is referred to as a murmur. An x ray of the chest will show the right atrium to be enlarged. Further support for this diagnosis is found on an echocardiogram of the heart, which will show an image of the stenotic valve and measure its severity.

Treatment

Tricuspid valve stenosis itself usually does not require treatment. However, if there is damage to other valves in the heart as well, then surgical repair or replacement must be considered.

Since a person with known tricuspid valve stenosis is at risk for infections of the heart, **antibiotics** should be taken before and after oral or dental surgery, or urologic procedures.

Prognosis

Mild tricuspid valve stenosis is not usually considered cause for surgery. The decision to repair or replace the tricuspid valve is often based on the health of the aortic and mitral valves, rather than on the severity of stenosis in the tricuspid valve.

Prevention

Rheumatic **fever**, the usual cause of tricuspid valve stenosis, has almost disappeared in North America and western Europe. Therefore, the number of people who acquired this condition in childhood will decline over time.

Trigeminal neuralgia

Trigeminal **neuralgia** is a disorder of the trigeminal nerve (the fifth cranial nerve) that causes episodes of sharp, stabbing **pain** in the cheek, lips, gums, or chin on one side of the face.

Trigeminal neuralgia is a disorder of the trigeminal nerve (which is divided into three branches) that causes episodes of sharp, stabbing pain in the cheek, lips, gums, or chin on one side of the face. WWW.BOOKBAZ.IR

saliva and tears, and for sending facial sensations to the brain. When this nerve breaks down for some reason, it can trigger brief but agonizing sizzles of pain on one side of the face.

This condition is unusual in those under age 50 and more often occurs after 70. Women are three times more likely to have the condition than are men. When trigeminal neuralgia does occur in younger people, it is often associated with **multiple sclerosis**.

The pain, while brief, is so severe that the individual often cannot do anything else while the attack lasts. People with this pain often wince or twitch, which is where trigeminal neuralgia gets its French nickname *tic douloureux*, meaning "painful twitch."

Causes and symptoms

The origin of trigeminal neuralgia is not certain, but scientists believe it may be caused by degeneration, pressure, or irritation of the trigeminal nerve. Some doctors believe the pain may be triggered by pressure from a nearby abnormally-formed artery lying too close to the nerve.

Any part of the three branches of the trigeminal nerve may be affected. Neuralgia of the first branch leads to pain around the eyes and over the forehead; the second branch causes pain in the upper lip, nose and cheek; the third branch causes pain on the side of the tongue and lower lip.

The first episodes are usually fairly mild and brief, and it may be minutes, hours, or weeks before the next attack. However, attacks tend to occur in clumps that may last for weeks at a time. As the individual ages, the episodes become more frequent and painful, until the person begins to live in constant fear of the next one.

The momentary bursts of pain usually begin from the same spot on the face each time. The pain can be triggered by touching the area, washing, shaving, eating, drinking, or even talking. Even a cool breeze across the face can set off an attack. Pain is more severe at the ends of the affected nerve, especially over the lip, chin, nostrils, or teeth.

Diagnosis

Diagnosis is usually made by eliminating other problems that could cause similar pain in teeth, jaw, head, or sinuses. Because patients with the condition tend to avoid trigger points, avoiding chewing, shaving, touching or washing their faces can be a clue to diagnosis of trigeminal neuralgia.

KEY TERMS

Multiple sclerosis—A progressive disease of the central nervous system in which the coverings of nerves in the brain and spinal cord are destroyed.

Treatment

It is not easy to treat trigeminal neuralgia. Pain can be suppressed by a range of medicines, including the anti-epilepsy medicines carbamazepine (Tegretol) or phenytoin (Dilantin). These drugs slow down the nerve signals at certain nerve terminals, which eases the pain. However, these drugs cause a wide range of side effects, including nausea, **dizziness**, drowsiness, liver problems, and skin **allergies**. Some people develop resistance to the drugs or they cannot tolerate the high dosage needed to control the discomfort. If the medicines are stopped, the pain usually returns.

If drug treatment fails, surgical treatment to block pain signals from the nerve may be effective. Radio-frequency waves, gamma rays, or glycerol injections can deaden the nerve (and hence the pain). An operation that frees the nerve from whatever is compressing it (blood vessel or tumor) can permanently relieve pain, but this major neurosurgical procedure carries its own risks and complications. Alternatively, a new procedure seeks to place a cushioning sponge between the nerve and a pulsating artery wrapping around it to soothe the irritated nerve.

Prognosis

Although the pain is momentarily incapacitating, it is not life-threatening. As the person ages, the attacks can be expected to occur more and more frequently.

Prevention

While the condition itself cannot be prevented, there are a number of things patients can do to avoid triggering attacks:

- wash with cotton pads and warm water over the face
- rinse the mouth with water after eating, if tooth-brushing triggers pain
- eat and drink food and beverages at room temperature
- chew on the unaffected side
- eat soft foods, if eating is becoming a problem

KEY TERMS

Microcirculation—The passage of blood in the smallest blood vessels of the body, such as the capillaries in the hand and fingers.

Myofascial—The fibrous tissue that encloses and separates layers of muscles.

Nodule—A swelling or knob that may form on a tendon and make it difficult to slide smoothly through its sheath.

Stenosis—Narrowing of a passageway or opening in the body. In trigger finger it is the tendon sheath that narrows.

Synovial tendon sheath—Where the tendons cross joints, they are sheathed in thin membranes known as synovium, which provide lubrication to decrease friction.

Tendon sheath—A membrane covering a tendon.

Tenosynovitis—Inflammation of a tendon and its enveloping sheath, usually resulting from overuse injury.

Trigger finger

Definition

Trigger finger is the popular name of stenosing tenosynovitis, a painful condition in which a finger or thumb locks when it is bent (flexed) or straightened (extended).

Description

Tendons are tough, fibrous cords that connect muscles to bones. Tendons must slide easily through their protective coverings (tendon sheaths). The finger and thumb bones have tendons that are responsible for bending and straightening the fingers. Problems start when a tendon sheath narrows (stenosis) and the outer covering of the tendon becomes inflamed (tenosynovitis). The tendon swells because of the constriction, sometimes forming a nodule, and is no longer able to move smoothly through its sheath. As a result, a finger may lock in an upward position as the person tries to straighten it. The condition usually happens in the ring and middle fingers and is more common in women, typically over age 30. In infants and small children, the condition generally occurs in the thumb.

Causes and symptoms

Trigger finger is often an overuse injury because of repetitive or frequent movement of the fingers. Trigger finger may happen because a person performs the same manipulation over and over on a job, from squeezing and gripping during a weekend of heavy pruning and gardening, or from such hobbies as playing a musical instrument or crocheting. Trigger finger may also result from **trauma** or accident. The symptoms of trigger finger are **pain** in the fingers and "popping" sensations. Sometimes the finger may lock down into the palm or lock out straight. Symptoms are usually worse in the morning and improve during the day.

Diagnosis

The diagnosis of trigger finger and thumb is obvious on **physical examination**. Often there is a click that can be felt as the nodule passes through the sheath. Most cases are uncomplicated but x rays are often taken to rule out other injuries or disease such as arthritis.

Treatment

Initial treatment for mild or infrequent symptoms of trigger finger include rest, avoiding or modifying those activities that caused the inflammation, and the use of a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen. This may relieve the swelling and inflammation that resulted in the constriction of the sheath and the restriction of the tendon. Injection of a steroid medication (cortisone) into the tendon sheath is the next option to treat trigger finger. Depending on the severity, there may be one more injection a week later. Two-thirds of patients improve after one injection. Some physicians will splint the finger in extension after the injection.

WWW.BOOKBAZ.IR

In severe cases that do not respond to injections and the finger or thumb remains in a locked position, surgery may be required to relieve the symptoms. A local anesthetic is used for the surgical procedure performed on an outpatient basis. An incision is made by a surgeon in the palm of the hand at the base of the affected finger or thumb to relieve the constriction of the tendon. Recovery may take up to four weeks. Sometimes **physical therapy** of the hand is required after surgery to regain good use.

Alternatives

Treatment should begin when a person starts having difficulty moving the fingers. If started early, noninvasive measures have a good chance for success. Alternative treatments include **acupuncture** to facilitate healing and microcirculation, pulsed **ultrasound**, and myofascial release work for the affected area.

Prognosis

At least half of cases can be cured non-surgically. The key to successful treatment is early intervention. A mistake people make is trying to work through the pain. Diabetics have a higher incidence of the condition and are sometimes left with a disability.

Prevention

Taking frequent breaks from a repetitive activity will do much to prevent the condition. Depending on the intensity, that may mean a 10-minute break every hour from the repetitive activity. The break should be spent stretching the hands and arms and generally moving around.

Triglycerides

Definition

Triglycerides are a form of fat, consisting of three molecules (tri) of a fatty acid combined with one molecule of the alcohol glycerol. Triglycerides serve as the backbone of many types of lipids (fats). Triglycerides are produced by the liver as well as are ingested as part of the diet. Fats in foods are digested and changed to triglycerides.

Triglyceride levels

Normal	Less than 150 mg/dL
Borderline-high	150–199 mg/dL
High	200–499 mg/dL
Very high	500 mg/dL or above

SOURCE: National Heart, Lung and Blood Institute, National Institutes of Health, U.S. Department of Health and Human Services

Healthy (normal) and unhealthy triglyceride levels. *(Table by PreMediaGlobal. © Cengage Learning®.)*

Purpose

Triglycerides have several purposes in **physiology**. Triglycerides travel through the circulatory system and are either utilized immediately or are stored in adipose tissue, thereby serving as the most abundant form of stored energy in the body. Triglycerides can serve as this important storage medium because of their hydrophobicity, which allows them to be stored as droplets, without contact with water molecules. Often a typical human body may contain several months of fuel stored in the form of triglycerides. When physiological conditions dictate the need to use the triglycerides, hormones or a neurotransmitter signal their release. This release may be in response to **exercise**, **stress**, or **fasting**. An enzyme called lipase breaks down the triglyceride molecule into a glycerol molecule and three fatty acids before release from the adipose tissue. These breakdown products are transported within the circulatory system to the tissues that need them for energy.

In addition to serving as a source of energy, triglycerides carry the fat-soluble **vitamins** (including **vitamin K**, an important nutrient in normal blood coagulation). Triglycerides also provide thermal insulation and contribute to the structure of membranes by the formation of a lipid bilayer.

Triglycerides combine with a blood protein to form chemicals referred to as high-density and low-density lipoproteins. These lipoproteins contain **cholesterol**, another substance related to fats.

Description

It is not yet clear whether high triglyceride levels act as a predictor of the risk for **heart disease** and heart attacks, especially in persons with normal levels of cholesterol. Some healthcare professionals feel that elevated triglycerides are a marker for other risk factors that do impact the risk of heart disease, that is, high levels of triglycerides are usually associated with low levels of **high density lipoproteins**, usually referred to as the "good" cholesterol.

However, there are some indications that high triglycerides may serve as a predictor for heart disease, especially in women. In a study involving postmenopausal women (aged 48–76 years old) conducted by a research group from the Center for Clinical and Basic Research in Ballerup, Denmark, it was found that women who had an enlarged waist and elevated levels of triglycerides had almost a five-fold increased risk of fatal cardiovascular events compared to women without those traits. The women at risk deposited fat centrally in their intra-abdominal compartment, rather than in their hips, thighs, and buttocks.

The mechanism of how triglycerides might affect heart health is not fully known, but it appears that elevated levels of triglycerides may allow increased blood clot formation and may slow the natural breakdown of clots after they have formed. High levels of triglycerides may mean an increased risk of diabetes, and very high levels of triglycerides may increase the risk of inflammation of the pancreas, resulting in **pancreatitis**.

Triglyceride levels are evaluated through blood testing. A fatty meal that is high in triglycerides will cause a short term increase in blood triglyceride levels. Therefore, before testing, a person should refrain from eating food 8–10 hours before the test and not drink alcohol for 24 hours before the test. Some medications may interfere with test results, and the healthcare provider may request that the person cease taking the medications before testing. For example, **oral contraceptives**, estrogen, and cholestyramine (a drug used to treat high cholesterol levels) may increase blood triglyceride levels, while vitamin C (ascorbic acid), asparaginase (an enzyme used in the treatment of cancer), and various drugs to treat high levels of blood lipids may decrease blood triglyceride levels. Triglyceride levels can also be affected by the menstrual cycle, time of day, and recent exercise. A person should have two or three tests, one week apart, for the most accurate results.

The normal range of blood triglyceride levels depends on age and gender, with women naturally having higher levels, especially when pregnant. As people age and gain weight, triglyceride levels usually increase. According to the guidelines promulgated by the National Cholesterol Education Program, a division of the National Heart, Lung, and Blood Institute, a normal fasting level for adults is less than 150 milligrams per deciliter (mg/dL), with levels below 101 considered desirable. Levels of 150–199 mg/dL are considered borderline high, levels of 200–499 mg/dL are considered high, with levels greater than 500 mg/dL considered very high. Such high levels may indicate **liver disease** (**cirrhosis**), underactive thyroid activity, uncontrolled diabetes, pancreatitis, **kidney disease**, or a diet too low in protein and too high in carbohydrates.

Extremely low levels of triglycerides (less than 10 mg/dL) may indicate **malnutrition**, malabsorption, a diet too low in fat, or an overactive thyroid.

High triglyceride levels may be due to several causes, including:

- Lifestyle factors
- Weight gain
- Lack of exercise
- Smoking
- Skipping meals
- Eating large portions of food at one time
- Dietary factors
- Excessive intake of alcohol, saturated and trans fats, sugar, starch, and calories
- Medical conditions
- Medicines, including birth control pills, steroids, and diuretics
- Illnesses, including poorly controlled diabetes, insulin resistance (a precursor to diabetes), polycystic ovary syndrome (PCOS), hypothyroidism, kidney disease, and liver disease
- Age

Hereditary may also play a role in elevated levels of triglycerides. Familial hypertriglyceridemia is a common inherited disorder in which the level of triglycerides in a person's blood is higher than normal. This disorder is an autosomal dominant disorder, that is, if one parent has an abnormal gene and the other parent a normal gene, there is a 50% chance each child will inherit the abnormal gene and, therefore, the dominant trait. Some people with this condition also have high levels of very low density lipoprotein (VLDL), the "bad" cholesterol. **Obesity**, hyperglycemia (high blood glucose levels), and high levels of insulin are often associated with this condition and may result in even higher triglyceride levels.

WWW.BOOKBAZ.IR

Familial hypertriglyceridemia is not usually detected until **puberty** or early adulthood. Symptoms include a mild-to-moderate increase in blood triglyceride levels and premature **coronary artery disease**. Persons with this condition are also at increased risk for pancreatitis.

Familial hypertriglyceridemia occurs in about 1 in 500 individuals in the United States. Risk factors are a family history of hypertriglyceridemia or a family history of heart disease before the age of 50. If triglyceride levels cannot be not controlled by dietary and lifestyle changes, medication may be needed. Nicotinic acid and gemfibrozil have been shown to effectively reduce triglycerides in persons with familial hypertriglyceridemia. Screening family members for elevated levels of triglycerides may help to detect the disease early.

A nutritionist or dietitian may be consulted to help develop a dietary plan to help control triglyceride levels. In general, to lower or prevent high levels of triglycerides, a person should:

- Lose weight
- Get regular exercise
- Eat less sugar and sugar-containing foods
- Eat smaller meals and snacks throughout the day, rather than consuming two or three large meals
- Drink less alcohol (even small amounts of alcohol has been shown to elevate triglycerides)
- Limit fat in the diet to less than 35% of daily calories
- Avoid deep-fried foods
- Substitute monounsaturated and polyunsaturated fats, such as those found in canola or olive oils, for saturated fats
- Use a prescription medicine, as directed by the healthcare provider, to decrease the production of triglycerides by the liver
- Consume fish high in omega-3 fatty acids, such as salmon, lake trout, herring, sardines, albacore tuna, or mackerel (about 10–15 g of fish oil a day is recommended; 15 g of fish oil can be obtained from an 8-oz. [227 g] serving of fish)

Other good food choices include fruits (but not fruit juices, which are high in sugar); vegetables; whole grain breads and cereals; lean protein sources, such as lean meats, poultry without skin, eggs, egg substitute or egg white, cooked dried beans, lentils, peas, nuts, and low-fat soy products; fat-free or 1% milk products; nuts such as almonds, walnuts, and peanuts; avocados; and sugar-free products.

One approach to successfully changing the diet to reduce blood triglyceride levels is to make changes in stages. For example, individuals could cut fat intake to 30% for one month (current American levels are approximately 40%) and then return to their healthcare provider to see if there has been an improvement in their triglyceride levels. If the level of decrease was not satisfactory, the individual could further restrict their fat intake to 25% and again be evaluated after one month. If no improvement is noted, the fat intake should be lowered to 20% for two months. At this level of fat intake, it is likely that most calories are being obtained from complex carbohydrates, and a reduction in triglyceride levels should be seen.

Risks

Other risk factors for coronary heart disease can increase the hazards from high levels of triglycerides. Therefore, in addition to making dietary changes a person with high levels should also control high blood pressure and avoid cigarette **smoking**. Dietary management is important even when drugs are used to control triglyceride levels.

Triglycerides test

Definition

Triglycerides test is a blood test to determine the amount of triglycerides, a form of fat, in the blood.

Purpose

The triglycerides test is one of the screening tests for excess lipids (fats) in the blood. It is usually part of an evaluation of risk factors for **heart disease**.

Description

Triglycerides are a form of fat that comes from foods. They can also be made and stored in the body and are used as an energy source. High levels of triglycerides in the blood can mean that there is too much fat in the diet. Hypertriglyceridemia (high levels of triglycerides) is associated with coronary heart disease, especially since elevated triglycerides levels are often associated with unhealthy low levels of hyperdensity lipoproteins (the "good" **cholesterol**), which are necessary for good health.

Preparation

For triglycerides testing, blood is drawn from a vein in the arm. A vein at the inside of the elbow or on the back of the hand is usually selected. The area where the needle will be inserted is cleaned with antiseptic. A small needle is inserted through the skin and into the vein, allowing a small amount of blood to flow into a collection tube or syringe. Once the blood is collected, the needle is removed from the puncture site.

Before the blood test, the patient may be required to refrain from eating food for 8–12 hours. Patients should not drink alcohol for 24 hours before the test. Some drugs may affect the test and the patient may be asked to cease taking certain medications before the test. **Oral contraceptives**, estrogen, and cholestyramine (a drug used to treat high cholesterol) can increase triglyceride levels. Ascorbic acid (vitamin C), asparaginase (an enzyme), and various drugs used to treat high blood lipids, can decrease blood triglyceride levels. These substances should not be taken prior to this test.

Aftercare

After the blood sample has been taken and the needle withdrawn from the puncture site, a cotton ball or gauze pad may be placed over the site and direct pressure applied to reduce bleeding. A piece of surgical tape or gauze adhesive bandage strip may be secured over the site to prevent further bleeding.

Risks

There is a very small risk that the puncture site may bleed excessively, a bruise or infection may develop at the site, or it may take several punctures to locate a vein. Some patients may feel faint or lightheaded when blood is drawn.

Results

The normal range of triglycerides in the blood depends on the age and gender of the patient. Women naturally have higher levels of triglycerides than men. **Pregnancy** can also increase triglyceride levels. As people age and gain weight, triglyceride levels generally increase. For adults, a normal level is considered to be less than 200 mg/dL (milligrams per deciliter). Levels from 200–400 mg/dL are considered borderline high.

Abnormal results

Triglyceride levels ranging from 400-1,000 mg/dL are considered high and levels greater than 1,000 mg/dL are considered very high. High levels of triglycerides may indicate **liver disease** (**cirrhosis**), an underactive thyroid problem, uncontrolled diabetes, an infection of the pancreas (**pancreatitis**), **kidney disease**, or a diet too low in protein and too high in carbohydrates.

Extremely low triglycerides levels (less than 10 mg/dL) can also indicate a problem. Low levels may indicate **malnutrition** (not enough nutrients in the diet), malabsorption (inadequate absorption of nutrients in the intestinal tract), a diet too low in fat, or an overactive thyroid problem.

Tropical spastic paraparesis

Definition

Tropical spastic paraparesis (TSP) is an incurable viral infection of the spinal cord that causes weakness in the legs. It is caused by the human T-cell lymphotropic virus-1 (HTLV-1) retrovirus.

Description

As the name implies, tropical spastic paraparesis usually occurs in tropical locales. Although isolated cases have been diagnosed in the southeastern United States and other places in the United States, TSP is most frequently found in:

- the Caribbean
- Japan
- the Seychelles Islands
- regions of South America
- western Africa

TSP usually affects adults between the ages of 30 and 40, and is far more common in women than in men.

The disease may remain undetected for years after infection is contracted. When the immune system's response to the virus causes nerve damage, the legs gradually lose strength and flexibility.

Causes and symptoms

TSP is caused by the HTLV-1 virus, which also causes leukemia. The virus can be spread through the placenta, and also through blood transfusions, **breastfeeding**, contaminated needles, and sexual contact.

Symptoms may begin years after infection. In response to the infection, the body's immune response may injure nerve tissue, causing symptoms that include bladder abnormalities, leg **pain**, loss of feeling in the feet, tingling sensations, and unpleasant sensations when the skin is touched.

As many as 20% of patients with TSP may also experience:

- deafness
- double vision
- the tendency to incorrectly estimate the amount of motion necessary to accomplish a specific task (dysmetria)
- exaggerated reflexes
- facial paralysis
- tremor

Diagnosis

Infectious disease specialists use blood tests and **magnetic resonance imaging** (MRI) of the spinal cord to diagnose this condition.

Treatment

While the disease is incurable, significant improvement has been reported in the condition of TSP patients treated with **corticosteroids**. These drugs are believed to alleviate symptoms by suppressing the immune system's response to the virus that causes them.

Plasmapheresis, a dialysis-like procedure in which symptom-producing antibodies are removed from the blood, also provides temporary relief.

Prognosis

TSP cannot be cured.

Prevention

The U.S. Food and Drug Administration (FDA) has approved screening procedures developed to detect

HTLV-1 in donated blood and blood products designated for **transfusion**. These procedures, which can also be used to diagnose patients with TSP, are designed to prevent the spread of the disease.

Troponins test

Definition

Troponins are specific proteins found in heart muscle. Troponin testing is done to diagnose heart attacks (myocardial infarctions).

Purpose

When heart muscle is damaged, as in a myocardial infarction (MI), troponins leak out of cells and into the bloodstream. Increased troponin levels indicate myocardial infarction or injury in a person with chest **pain** or pressure. Some MIs are silent, manifesting few if any symptoms.

If infarction is ruled out in a person with continuing or recurring chest pain (unstable **angina**), an increased troponin level indicates the person has heart muscle ischemia (a decreased supply of oxygenated blood to the body), and is at an increased risk for a future serious heart event.

Description

Although troponins also exist in other muscles, those in the heart are unique, and are measured separately in laboratory tests. Troponins in the heart are called cardiac troponins. There are two main types of cardiac troponins; T and I. T is also referred to as cTnT, while I is also referred to as cTnI.

Both troponin T and I are cardiac markers used to diagnose myocardial infarctions. Cardiac markers are substances whose blood levels increase after a myocardial infarction. Others include CK (creatine kinase), myoglobin, and CK-MB (one of three CK isoenzymes).

KEY TERMS

Angina—A temporary chest pain caused by the heart not receiving enough oxygen.

Cardiac marker—A substance in the blood whose level rises following a myocardial infarction.

Myocardial infarction—Commonly known as a heart attack, a myocardial infarction is an episode in which some of the heart's blood supply is severely cut off or restricted, causing the heart muscle to weaken and die from lack of oxygen.

Like all cardiac markers, troponins have a unique diagnostic window (the timeline during which the marker rises, peaks, and returns to normal). Troponin levels rise within four to six hours after the beginning of chest pain or heart damage, and stay elevated for at least one week. This long elevation allows detection of a myocardial infarction that occurred days earlier, but prevents detection of a second infarction if it occurred only days after the first.

Troponins I and T are considered superior cardiac markers for several reasons. The most significant is that cardiac troponins are the only markers specific for heart muscle. Other markers also increase following damage to other muscles. Troponin levels help predict the extent of heart muscle damage; higher levels are associated with increased damage, lower levels with less damage. Levels in a healthy person are negligible, so an increase is easily detected.

The main difference between troponins I and T is that cardiac troponin I tests measure only cardiac troponin; tests for cardiac troponin T may cross-react with troponin found in other muscles and give positive or increased results in the absence of heart damage.

Two types of tests for troponins T and I are available: a traditional quantitative test that provides an actual measurement of troponin, and a newer qualitative test that simply reports the result as positive or negative. The quantitative test takes 45–90 minutes, and helps distinguish between myocardial infarction and unstable angina. The qualitative test takes 15 minutes and is used in emergency rooms in which rapid patient care decisions can be made based on the presence or absence of troponins.

Preparation

Troponins tests require 5 mL of blood. Collection of the sample takes only a few minutes.

WWW.BOOKBAZ.IR

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Results

People without heart damage have troponin levels less than 0.5 ng/mL.

Abnormal results

Levels greater than 2.0 ng/mL indicate a person has had a significant myocardial injury, such as an infarction, and is at an increased risk for future serious heart events. Levels between 0.5 and 2.0 ng/mL indicate a diagnosis of unstable angina, other heart disorders, or **chronic kidney failure**.

Tubal ligation

Definition

Tubal ligation is a permanent voluntary form of birth control (**contraception**) in which a woman's fallopian tubes are surgically cut, tied, or blocked off to prevent **pregnancy**. It is important that women understand that tubal ligation prevents only pregnancy, not sexual transmitted infections (STI). Barrier methods are still needed to prevent STIs.

Purpose

Tubal ligation is performed in women who want to prevent future pregnancies. It is frequently chosen by women who do not want more children, but who are still sexually active and potentially fertile and want to be free of the limitations of other types of birth control. Women who should not become pregnant for health concerns or other reasons may also choose this birth control method.

Demographics

Tubal ligation is one of the leading methods of contraception. This form of contraception is chosen by about 650,000–700,000 annually in the United States. The typical tubal ligation patient is over age 30, is married, and has already had two or three children.

Description

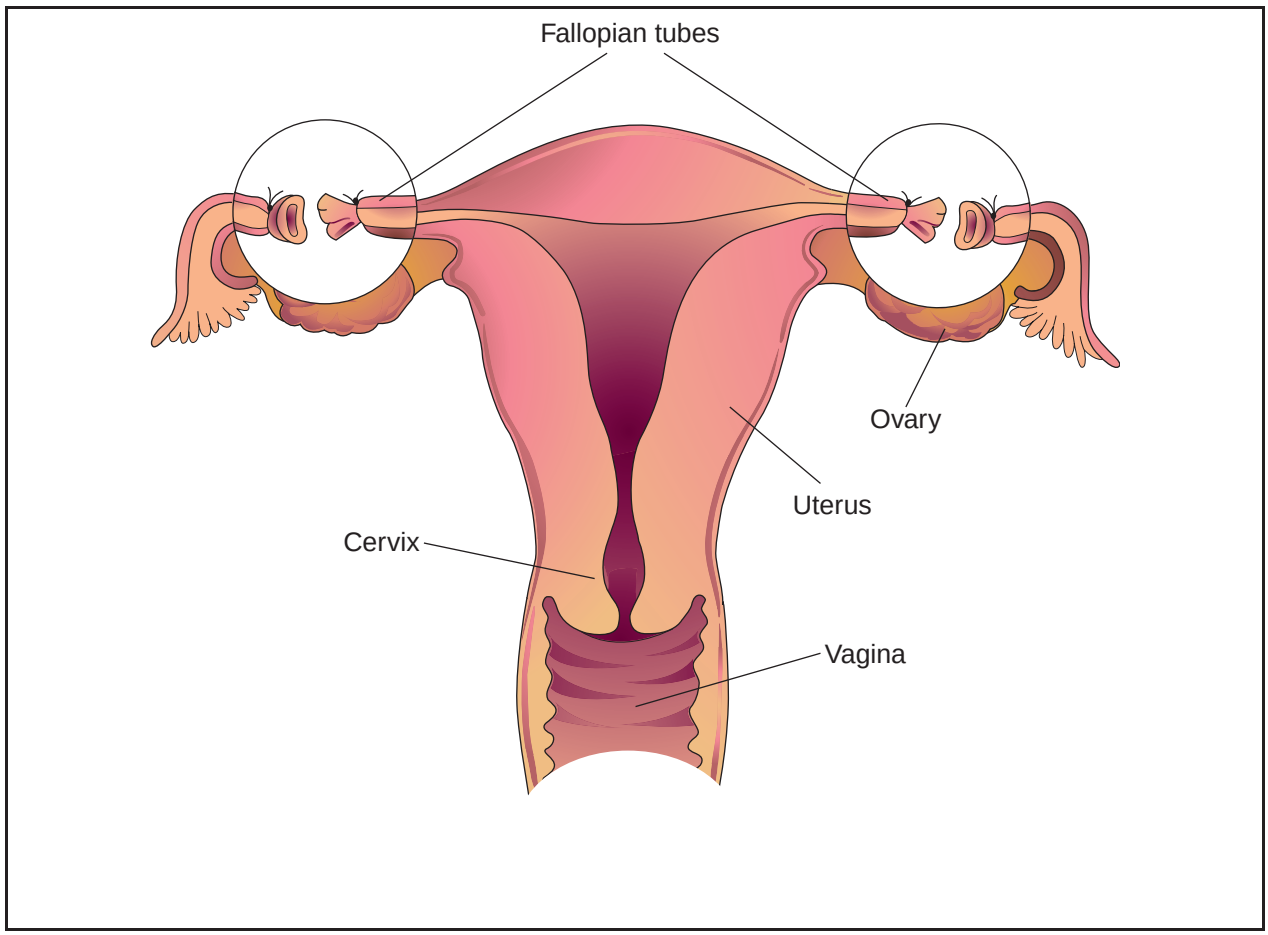
Tubal ligation is generally performed by an obstetrician/gynecologist, a medical doctor who has completed specialized training in the areas of women's general health, pregnancy, labor and childbirth, prenatal testing, and genetics. The procedure is performed in a hospital or family planning clinic, usually as an outpatient procedure.

Tubal ligation refers to female sterilization, the surgery that ends a woman's ability to conceive. The operation is performed on the patient's fallopian tubes. These tubes, which are about 4 in. (10 cm) long and 0.2 in. (0.5 cm) in diameter, are found on the upper outer sides of the uterus. They open into the uterus through small channels. It is within the fallopian tube that fertilization, the joining of the egg and the sperm, takes place. During tubal ligation, the tubes are cut or blocked in order to close off the sperm's access to the egg.

Normally, tubal ligation takes about 20–30 minutes, and is performed under general **anesthesia**, spinal anesthesia, or local anesthesia with **sedation**. The surgery can be performed on either hospitalized patients within 24 hours after **childbirth** or on outpatients. The woman can usually leave the hospital the same day.

The most common surgical approaches to tubal ligation include **laparoscopy** and mini-laparotomy. In a laparoscopic tubal ligation, a long, thin telescope-like surgical instrument called a laparoscope is inserted into the pelvis through a small cut about 0.5 in. (1 cm) long near the navel. Carbon dioxide gas is pumped in to help move the abdominal wall to give the surgeon easier access to the tubes. Often, the surgical instruments are inserted through a second incision near the pubic hair line. An instrument may be placed through the vagina to hold the uterus in place.

In a mini-laparotomy, a 1.2–1.6 in. (3–4 cm) incision is made just above the pubic bone or under the navel. A larger incision, or laparotomy, is rarely used today. Tubal ligation can also be performed at the time of a **cesarean section**.



Tubal ligation is a permanent form of contraception in which a woman's Fallopian tubes are surgically cut, cauterized, tied, or blocked to prevent pregnancy. This procedure blocks the pathway sperm takes to fertilize an egg. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Surgical tubal ligation itself is performed in several ways, including:

- Electrocoagulation. A heated needle connected to an electrical device is used to cauterize or burn the tubes. Electrocoagulation is the most common method of tubal ligation.
- Falope ring. In this technique, an applicator is inserted through an incision above the bladder and a plastic ring is placed around a loop of the tube.
- Hulka clip. The surgeon places a plastic clip across a tube held in place by a steel spring.
- Silicone rubber bands. A band placed over a tube forms a mechanical block to sperm.

Tubal ligation costs between $1,500 and $6,000 when performed by a private physician, but is less expensive when performed at a family planning clinic. Most insurance plans cover treatment costs.

Precautions

Tubal ligation should be postponed if the woman is unsure about her decision. While the procedure is sometimes reversible, it should be considered permanent and irreversible. As many as 10% of sterilized women regret having had the surgery, and about 1% seek treatment to restore their fertility.

Preparation

Preparation for tubal ligation includes patient education and counseling. Before surgery, it is important that the woman understands the permanent nature of tubal ligation as well as the risks of anesthesia and surgery. Her medical history is reviewed, and a **physical examination** and laboratory testing are performed. The patient is not allowed to eat or drink for several hours before surgery.

WWW.BOOKBAZ.IR

Aftercare

After surgery, the patient is monitored for several hours before she is allowed to go home. She is instructed on care of the surgical wound, and what signs to watch for, such as **fever**, nausea, **vomiting**, faintness, or **pain**. These signs could indicate that complications have occurred.

Risks

While major complications are uncommon after tubal ligation, there are risks with any surgical procedure. Possible side effects include infection and bleeding. After laparoscopy, the patient may experience pain in the shoulder area from the carbon dioxide used during surgery, but the technique is associated with less pain than mini-laparotomy, as well as a faster recovery period. Mini-laparotomy results in a higher incidence of pain, bleeding, bladder injury, and infection compared with laparoscopy. Patients normally feel better after three to four days of rest, and are able to resume sexual activity at that time.

The possibility for treatment failure is very low—about 5 women per 1,000 will become pregnant during the first year after sterilization. The failure rate increases over time, so that ten years after the procedure, the failure rate is 18 women per 1,000. Failure can happen if the cut ends of the tubes grow back together; if the tube was not completely cut or blocked off; if a plastic clip or rubber band has loosened or come off; or if the woman was already pregnant at the time of surgery.

Results

After having her tubes tied, a woman does not need to use any form of birth control to avoid pregnancy. Tubal ligation is almost 100% effective for the prevention of conception.

Morbidity and mortality rates

About 1–4% of patients experience complications following tubal ligation. There is a low risk (less than 1%, or 7 per 1,000 procedures) of a later **ectopic pregnancy**. Ectopic pregnancy is a condition in which the fertilized egg implants in a place other than the uterus, usually in one of the fallopian tubes. Ectopic pregnancies are more likely to happen in younger women, and in women whose tubes were closed off by electrocoagulation.

Rarely, death may occur as a complication of general anesthesia if a major blood vessel is cut. The mortality rate of tubal ligation is about 4 in 100,000 sterilizations.

Post-ligation regret is a very real issue for some women. Women under the age of 20 have rates as high as 20%, while those over 30 have 6% regret rates. Because of these issues, it is crucial that women receive adequate and sensitive counseling prior to undergoing tubal ligation.

KEY TERMS

Contraception—The prevention of the union of the male's sperm with the female's egg.

Ectopic pregnancy—The implantation of a fertilized egg in a fallopian tube instead of the uterus.

Electrocoagulation—The coagulation or destruction of tissue through the application of a high-frequency electrical current.

Female sterilization—The process of permanently ending a woman's ability to conceive by tying off or cutting apart the fallopian tubes.

Laparoscopy—Abdominal surgery performed through a laparoscope, which is a thin telescopic instrument inserted through an incision near the navel.

Laparotomy—A procedure in which the surgeon opens the abdominal cavity to inspect the patient's internal organs.

Vasectomy—Surgical sterilization of the male, done by removing a portion of the tube that carries sperm to the urethra.

Alternatives

There are numerous options available to women who wish to prevent pregnancy. **Oral contraceptives** are the second most common form of contraception—the first being female sterilization—and have a success rate of 95–99.5%. Other methods of preventing pregnancy include **vasectomy** (99.9 effective) for the male partner; the male condom (86–97% effective); the diaphragm or cervical cap (80–94% effective); the female condom (80–95% effective); and abstinence.

Fallopian tube implants

Another nonsurgical but permanent method of contraception is fallopian tube implants, which involves inserting metal springs into the fallopian tubes to block the passage of an egg. Over the course of about three months, this implant stimulates an inflammatory and fibrotic response that results in

blockage of the tubes, preventing sperm from reaching and fertilizing the eggs. The procedure is done on an outpatient basis and does not usually take more than 30–60 minutes. During the procedure, the woman is placed in the same position as during a yearly **pelvic exam**. On occasion a physician may insert laminaria into the cervix several hours prior to the procedure to gradually open the cervix. Laminaria are small sticks of dehydrated seaweed that slowly absorb moisture and gradually expand to open the cervix. If laminaria is not used prior to the procedure, then during the procedure, instruments are used to gradually open the cervix. A catheter is placed through the cervical opening and into the fallopian tube, where the small metal spring is placed. This is repeated for the other fallopian tube. After the procedure, an x ray is performed to make sure that both implants are properly placed, and a follow-up visit should be scheduled for three months after insertion. Fallopian tube implant placement requires the use of other contraceptive methods for at least three months. A diagnostic test is then performed to verify that the tubes are completely blocked, and that adjunct contraceptive methods are no longer necessary.

Tube compression of the esophagus and stomach

Definition

Tube compression of the esophagus and stomach is an emergency procedure used to stop bleeding from the upper digestive tract.

Purpose

Vomiting blood is both frightening and life-threatening. Among its causes are:

- bleeding from the nose and throat
- peptic ulcers
- stomach cancer
- esophageal cancer
- a tear in the esophagus caused by violent vomiting (Mallory-Weiss syndrome)
- breaking of blood vessels in the esophagus.

The most profuse bleeding comes from veins in the lower esophagus, just above the stomach, that have dilated to enormous dimensions as the result of **liver disease**. When the liver shrinks due to **cirrhosis** (scarring from chronic disease), its blood vessels shrink, forcing blood from the intestines to find alternate routes back to the heart. The blood usually flows through tiny veins in the esophagus located just beneath the passageway where food passes downward and vomitus passes upward. Major causes for this rearrangement are alcoholic liver disease, chronic hepatitis, and **cholangitis**. Called esophageal varices, the affected veins can be easily damaged and bleed voraciously.

Description

One emergency method of stopping bleeding from esophageal varices is to tamponade it with a balloon. The Sengstaken-Blakemore tube is a complex rubber device with two balloons and three channels—one channel for each balloon and one that goes all the way through. The Minnesota tube has four channels, an extra one that opens above the first balloon. The bottom balloon is round; the upper balloon is long and narrow. The tube is passed through the nose or mouth into the stomach, where the bottom balloon is inflated. Then the tube is pulled back until the bottom balloon comes up against the narrow valve at the top of the stomach, when it can go no further. At this point, the upper balloon is inflated, putting pressure on a length of esophagus where the bleeding veins are located. The tube is then fixed so it cannot be dislodged. The third channel in the tube is used to aspirate (suck out)

KEY TERMS

Cholangitis—Inflammation of the system of tubes that drains bile from the liver into the intestines.

Chronic hepatitis—Long lasting inflammation of the liver due to viruses or other causes.

Peptic ulcers—Wounds in the stomach and duodenum caused by stomach acid and the bacterium *Helicobacter pylori*.

Tamponade—To occlude by pressure.

stomach contents to see if the bleeding has stopped. The fourth channel aspirates from the esophagus.

These tubes are a temporary measure. They stabilize the patient until bleeding has stopped, blood transfusions are received, and permanent repair is imminent.

Since the lower balloon effectively separates the esophagus from the stomach, it is possible to determine more accurately where the bleeding is located when it is in place.

This method of treating upper intestinal bleeding is being replaced by procedures that use a gastroscope, a flexible device that permits viewing and operating without surgery.

Preparation

The procedure is explained to the patient and family. A sedative may be given to prepare the patient for the procedure.

Aftercare

With the tube in place, the patient cannot eat and may have some difficulty breathing. The patient will be hospitalized until the tube can be removed.

Risks

Major complications frequently occur, and death results about 3% of the time. Problems include damage to the esophagus and stomach and interference with the airway. Should the tube remain in place too long, there is danger of the pressure eroding the esophagus or the nose.

Tube feedings

Definition

Nutrients, either a special liquid formula or pureed food, are delivered to a patient through a tube directly into the gastrointestinal tract, usually into the stomach or small intestine.

Purpose

Tube feeding provides **nutrition** to patients who are unable or unwilling to eat food. Conditions where tube feeding is considered include **protein-energy malnutrition**, liver or kidney failure, **coma**, or in patients who cannot chew or swallow (dysphagia) due to **stroke**, **brain tumor**, or **head injury**. Patients who are receiving **radiation therapy** or **chemotherapy** treatments for cancer may also be candidates for tube feedings.

Precautions

Certain medications may interact with some formulas to inactivate the nutrients or change the way that the drug is absorbed.

Description

A flexible, narrow tube is inserted into some portion of the digestive tract and liquid formulas or liquefied foods are placed into the tube to meet the patient's nutritional needs. The feeding may be pumped into the tube or allowed to drip into the tube continuously or at scheduled feeding times.

A feeding tube can be inserted by a surgical or nonsurgical procedure in several positions along the gastrointestinal tract. A **nasogastric tube** is inserted through the nose with the end of the tube reaching into the stomach. A nasoduodenal or nasojejunal tube is inserted through the nose and ends in either the duodenum or jejunum, both of which are portions of the small intestine. This type of tube placement is usually used for short-term feeding. Surgical placement of a feeding tube may be done if there will be a long-term need for feeding that bypasses the upper digestive tract. An esophagostomy creates an opening in the esophagus, a **gastrostomy** creates an opening into the stomach, and a jejunostomy creates an opening into the jejunum. The feeding tube is then inserted through the surgically created opening.

Tube feedings can be a mixture of regular foods that are blended with liquid to make a consistency

that will pass through the tube. Nutritionally balanced liquid products are often more convenient to use and ensure a balance of proteins, fats, and carbohydrates along with **vitamins** and **minerals**. Specialized formulas are also available to meet almost any nutritional need. For example, patients with severe **burns**, protein-energy **malnutrition**, or slow wound healing may require formulas that are higher in protein. Patients with renal failure may require low-protein formulas with lower concentrations of minerals and vitamins.

Preparation

The reasons that tube feeding is necessary are discussed with the patient, as is the length of time that the feeding tube is expected to be in place. The specific procedure is also explained to the patient.

Aftercare

Patients with **ostomy** feeding tubes may have the tube positioned level with the surrounding skin. A cap or button can be placed over the opening so that it can be more comfortably concealed under clothing. The opening and surrounding tissue need to be cleaned and inspected regularly to prevent infection. For patients with a tube inserted through the nose, daily nasal hygiene is important and the mouth and lips should be kept moist. Good mouth care is necessary for any patient with a feeding tube.

Risks

Formula from the tube can back up in the esophagus and be breathed into the trachea and lungs, causing aspiration **pneumonia**. The placement of the tube should be checked frequently and the head of the bed elevated during and after feeding to prevent the solution from moving back up the digestive tract. Feeding tubes can also become clogged and should be flushed regularly with water. If the feeding formula is too concentrated or given too fast, the patient may experience nausea, **vomiting**, cramping, and bloating. The feeding may need to be diluted with liquid or the rate at which it is given decreased. **Diarrhea** or **constipation** can occur if the feeding is not the right

KEY TERMS

Duodenum—The upper portion of the small intestine. It is approximately 10 in. (25 cm) long and extends from the stomach to the jejunum.

composition or does not provide enough liquid. The tube itself can irritate the nasal passage, esophagus, or surrounding tissues.

Results

A patient may be able to return to a normal diet of solid foods after short-term supplementation with formula through a feeding tube. In cases where long-term nutritional therapy is required, all of the patient's nutritional needs will have to be provided by the formula. The balance of fluids, calories, proteins, fats, vitamins, and minerals may need to be adjusted periodically.

Abnormal results

If formula feedings are not tolerated by the patient or are inadequate to meet his or her nutritional needs, the patient may need to receive nutrition through an intravenous line (**parenteral nutrition**). This type of therapy involves delivery of sterile nutrient solutions directly into the bloodstream through a needle inserted into a vein.

Tuberculin skin test

Definition

Tuberculosis (TB) is an airborne **infectious disease** caused by the bacterium *Mycobacterium tuberculosis*. Besides culturing in the laboratory, the two most common types of tests to screen for exposure to this disease are the Mantoux PPD tuberculin skin test, which is generally considered more reliable, and the older TB tine test, which is now rarely used. These tests are designed to help identify individuals who may have been infected by the tuberculosis bacterium. A diagnosis of active, infectious tuberculosis is never made solely based on the results of a TB skin test, but requires further testing, including a **sputum culture** and a **chest x ray**.

Purpose

Because TB is spread through the air, especially in poorly ventilated areas, it is more commonly found among people living in crowded conditions, such as jails, nursing homes, and homeless shelters. Often, a TB skin test will be given as part of a **physical examination** when a person is hiring a new employee, particularly for those individuals seeking employment in the healthcare or food service professions.

People can be exposed to or infected with TB without showing any symptoms or necessarily developing the disease. Individuals with normally functioning immune systems generally prevent the spread of the bacteria by "walling off" or encysting the bacteria within the body. To be at risk for infection a person must have or had close contact with someone who has active tuberculosis (such as a friend or family member). Persons who are more at risk for developing the TB infection overtly include those with a weakened immune system (immunocompromised), either from a chronic disease, such as HIV infection; or as a result of a tissue or organ transplant or other medical treatment designed to suppress the immune system. In addition, persons who are heavy users of crack cocaine or alcohol are more susceptible to TB than those who do not abuse these substances. Symptoms of tuberculosis include a persistent **cough**, **fever**, weight loss, night sweats, **fatigue**, and loss of appetite.

Precautions

Although the test is generally considered safe, it is important to inform the person conducting the test if the patient may be pregnant, has had a positive TB test in the past, or has had tuberculosis in the past. People who have had a positive TB test in the past will probably always have a positive test and should not be tested again.

There are several situations when the TB test results might not be accurate. These include situations involving people who:

- have had vaccinations (such as those for measles, polio, rubella or mumps) within the last four weeks

FLORENCE B. SEIBERT (1897–1991)

Dr. Florence Barbara Seibert *((c) BettmannCORBIS)*

Florence Barbara Seibert was born on October 6, 1897, in Easton, Pennsylvania, and was the second of three children. She was the daughter of George Peter Seibert, a rug manufacturer and merchant, and Barbara (Memmert) Seibert. At the age of three she contracted polio. Despite her resultant handicaps, she completed high school, with the help of her highly supportive parents, and entered Goucher College in Baltimore, where she studied chemistry and zoology. She graduated in 1918, then worked under the direction of one of her chemistry teachers, Jessie E. Minor, at the Chemistry Laboratory of the Hammersley Paper Mill in Garfield, New Jersey. She and her professor, having responded to the call for women to fill positions vacated by men fighting in World War I, coauthored scientific papers on the chemistry of cellulose and wood pulps.

A biochemist who received her Ph.D. from Yale University in 1923, Seibert is best known for her research on the biochemistry of tuberculosis. She developed the protein substance used for the tuberculosis skin test, the standard screening test for the disease. The substance was adopted as the standard in 1941 by the United States and a year later by the World Health Organization. In addition, in the early 1920s, Seibert discovered the cause for the sudden fevers that sometimes occurred during intravenous injections: bacteria in the distilled water that was used to make the protein solutions. She invented a distillation apparatus that prevented contamination. This research had great practical significance later when intravenous blood transfusions became widely used in surgery.

Seibert authored or coauthored more than a hundred scientific papers. Her later research involved the study of bacteria associated with certain cancers. Her many honors include five honorary degrees, induction into the National Women's Hall of Fame in Seneca Falls, New York (1990), the Garvan Gold Medal of the American Chemical Society (1942), and the John Elliot Memorial Award of the American Association of Blood Banks (1962).

Description

TB skin tests are usually given at a clinic, hospital, or doctor's office. Sometimes the tests are given at schools or workplaces and may be a pre-employment requirement. Many cities provide free TB skin tests and followup care. The Mantoux PPD tuberculin skin test involves injecting a very small amount of a substance called PPD tuberculin just under the top layer of the skin (intracutaneously). Tuberculin is a mixture of antigens obtained from the culture of *M. tuberculosis*. Antigens are foreign particles or proteins that stimulate the immune system to produce antibodies. Two different tuberculin preparations are available, Old Tuberculin (OT) and Purified Protein Derivative (PPD). The latter is the preferred testing substance. The test is usually given on the inside of the forearm about halfway between the wrist and the elbow, where a small bubble will form as the tuberculin is injected. The skin test takes just a minute to administer.

After 48–72 hours, the test site will be examined by a trained person for evidence of swelling. People who have been exposed to tuberculosis will develop an immune response, causing a slight swelling at the injection site. If there is a lump or swelling, the healthcare provider will use a ruler to measure the size of the reaction. Some **public health** physicians recommend using a 72-hour waiting period as a general practice on the grounds that a 48-hour waiting period yields a higher percentage of false negative test results.

The other method of TB skin test is called the multiple puncture test or tine test because the small test instrument has several small tines that lightly prick the skin. The small points of the instrument are either coated with dried tuberculin or are used to puncture through a film of liquid tuberculin. The test is read by

WWW.BOOKBAZ.IR

measuring the size of the largest papule. Because it is not possible to precisely control the amount of tuberculin used in the tine test, a positive test should be verified using the Mantoux test. For this reason, the tine test is not as widely used as the Mantoux test and is considered to be less reliable; it is no longer recommended for general use.

Preparation

There is no special preparation needed before a TB skin test. A brief personal history will be taken to determine whether the person has had tuberculosis or a TB test before, has been in close contact with anyone with TB, or has any significant risk factors. Directly before the test, the skin on the arm at the injection site is usually cleaned with an alcohol swab and allowed to air dry.

Aftercare

After having a TB skin test, it is extremely important to make sure that the patient keeps the appointment to have the test reaction read. The patient is instructed to keep the test site clean, uncovered, and to not scratch or rub the area. Should severe swelling, **itching**, or **pain** occur, or if the patient has trouble breathing, the clinic or healthcare provider should be contacted immediately.

Risks

The risk of an adverse reaction is very low. Occasionally, an individual who has been exposed to the TB bacteria will develop a large reaction in which the arm swells and is uncomfortable. This reaction should disappear in two weeks. A sore might develop where the injection was given, or a fever could occur, but these are extremely rare reactions.

It is possible that a person who has TB may receive a negative test result (called a "false negative") or a person who does not have TB may receive a positive test result (called a "false positive"). If there is some doubt, the test may be repeated or the person may be given a diagnostic test using a chest x ray and/or sputum sample culture test to determine whether the disease is present and/or active in the lungs.

Results

In people who have not been exposed to TB, there will be little or no swelling at the test site after 48–72 hours. This is a negative test result. Negative test results can be interpreted to mean that the person has not been infected with the tuberculosis bacteria or that the person has been infected recently and not enough time has elapsed for the body to react to the skin test. Persons become sensitive between two and ten weeks after the initial infection. As a result, if the person has been in contact with someone with tuberculosis, the test should be repeated in three months. Also, because it may take longer than 72 hours for an elderly individual to develop a reaction, it may be useful to repeat the TB skin test after one week to adequately screen these individuals. Immunocompromised persons may be unable to react sufficiently to the Mantoux test, and either a chest x ray or sputum sample may be required.

A newer test that appears to be preferable to the tuberculin skin test in evaluating patients who are HIV-positive is the enzyme-linked immunospot (ELISPOT) assay. A group of researchers in the United Kingdom found that the ELISPOT assay was more accurate than the PPD test in detecting active as well as latent tuberculosis in HIV-positive patients.

Abnormal results

A reaction of 5 mm of induration (swelling) is considered positive for the following groups:

- household contacts of persons with active tuberculosis
- AIDS patients
- persons with old healed tuberculosis on chest x ray
- organ transplant recipients.
- persons receiving immunosuppressive medications

A reaction of 10 mm of induration is considered positive in individuals with one or more of the following risk factors that are either reasons to have a higher exposure to TB and/or a condition that increases the risk for progression to active TB:

- foreign-born immigrants from Asia, Africa, or Latin America
- injection drug users and persons who abuse alcohol
- residents and employees of such high-risk congregate settings as hospitals, homeless shelters, and jails
- medically under-served low income populations
- TB laboratory personnel
- children younger than four years of age or infants, children or adolescents exposed to adults in high risk categories
- residents of long-term care facilities
- individuals with certain medical conditions that increase the risk of developing tuberculosis; these medical conditions include being 10% or more below ideal body weight, silicosis, chronic renal failure, diabetes

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—Any foreign particle or protein that causes an immune response.

Attenuated—Alive but weakened; an attenuated microorganism can no longer produce disease.

Cross-reaction—A positive reaction that occurs as a result of a person's exposure to other non-tuberculosis bacteria.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

Induration—An abnormally hard spot or area on the skin. The tuberculin skin test produces an induration at the test site in persons who have been exposed to TB.

Intracutaneous—Into the skin, in this case directly under the top layer of skin.

Mantoux or PPD test—Other names for a tuberculin skin test. PPD stands for purified protein derivative.

Tuberculin—A mixture of antigens obtained from the cultured bacteria that cause tuberculosis, *Mycobacterium tuberculosis*.

mellitus, high dose corticosteroid or other immunosuppressive therapy, some blood disorders like leukemia and lymphomas, and other cancer

Finally, a reaction of 15 mm of induration or greater is considered positive in those with no risk factors and are, therefore, at the lowest risk of developing TB.

A TB skin conversion is defined as an increase of 10 mm or greater of induration within a two year period, regardless of age.

A positive reaction to tuberculin may be the result of a previous natural infection with *M. tuberculosis*, infection with a variety of non-tuberculosis mycobacteria (cross-reaction), or tuberculosis **vaccination** with a live, but weakened (attenuated) mycobacterial strain. TB vacination is not done in the United States. Cross-reactions are positive reactions that occur as a result of a person's exposure to other non-tuberculosis bacteria. These tend to be smaller than those caused by *M. tuberculosis*. There is no reliable way of distinguishing whether a positive TB skin test is due to a previous vaccination against tuberculosis. Generally, however, positive results are not due to vaccination exposure because reactions in vaccinated people tend to be less than 10 mm, and an individual's sensitivity to tuberculin steadily declines after vaccination. If the skin test is interpreted as positive, a chest x ray will be performed to determine whether the person has active tuberculosis or whether the body has sufficiently handled the infection.

Tuberculosis

Definition

Tuberculosis (TB) is a chronic, potentially fatal contagious disease that most often affects the lungs but can affect other parts of the body. It is caused by a bacterium or tubercle bacillus *Mycobacterium tuberculosis*.

Description

Tuberculosis was the common disease called consumption until well into the twentieth century. In 1882, when the microbiologist Robert Koch discovered the tubercle bacillus that causes the disease, TB caused one out of every seven deaths in Europe. The tubercle bacillus is transmitted when an infected person coughs or sneezes and another person breathes in the infected droplets. The disease is not spread through kissing or other physical contact.

Before **antibiotics** were discovered in the mid-1900s, the only means of controlling the spread of TB was to isolate patients in sanatoriums or hospitals limited to patients with TB. This practice continues today in some countries. The effect of this pattern of treatment was to separate the study of tuberculosis from mainstream medicine. Entire organizations were set up to study not only the disease as it affected individual patients, but also its impact on society. At the beginning of the twentieth century, more than 80% of the population in the United States was infected with TB before age 20, and tuberculosis was the single most common cause of death. By 1938, there were more than 700 specialized TB facilities in the United States.

Tuberculosis spread widely in Europe as the result of the industrial revolution in the late nineteenth century when many people moved to towns where they lived in crowded, unsanitary conditions. The disease became widespread somewhat later in the United States. In the early 1940s, with the discovery of streptomycin, the first antibiotic effective against *M. tuberculosis*, the infection began for the first time to be contained. Although other more effective anti-tuberculosis drugs that continue to reduce the number of TB cases have been developed in the past half-century, reports of active TB cases in the United States began to increase in the mid-1980s. This upsurge was in part a result of overcrowding and unsanitary conditions in the poor areas of large cities, in prisons, and in homeless shelters. Infected visitors and immigrants to the United States also contributed to the resurgence of TB. An additional factor was the **AIDS** epidemic. Individuals with HIV/AIDS are much more likely to develop tuberculosis because of their weakened immune systems than healthy individuals.

Risks

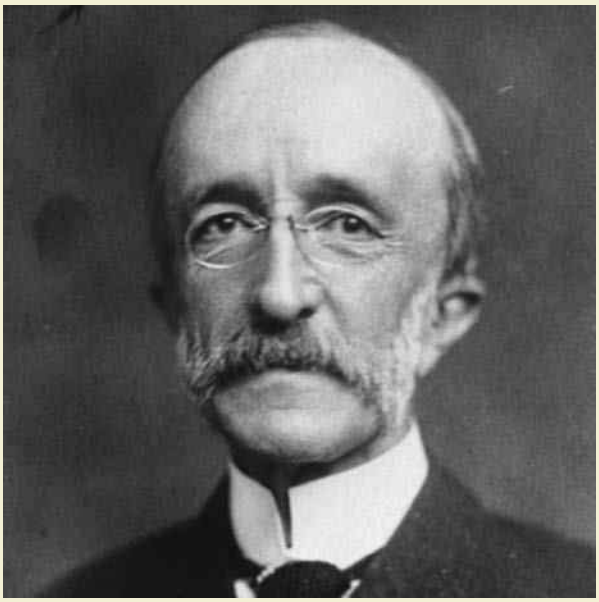
Americans at high risk for tuberculosis include:

- Elderly individuals. About one-quarter of TB cases newly diagnosed occur in people over age 65. Many elderly individuals developed TB after acquiring a latent TB infection years earlier. As they age, their immune systems can no longer control the disease, and they develop active TB symptoms. In addition, elderly people living in nursing homes and other group facilities are often in close contact with others who may be infected.
- People of color. In the United States, tuberculosis is more common in individuals who are non-white. Health researchers believe that this likely is related to the socioeconomic status of these groups rather than to race-related biological factors. Individuals of lower socioeconomic status tend to live in more crowded conditions and have less access to healthcare than higher socioeconomic status individuals, conditions which encourage the infection with *M. tuberculosis*.
- Certain immigrant groups that come from countries where TB infection is common. California, New York, Texas, and Florida, which are all states with large immigrant populations, accounted for almost half of all active TB cases. The most common countries of origin for foreign-born persons in the United States with active TB were Mexico, the Philippines, Vietnam, India, and China.
- AIDS patients, and those infected by human immunodeficiency virus (HIV) who have not yet developed clinical signs of AIDS but whose immune systems are weakened by the virus.
- People who take drugs that suppress the immune system (e.g., transplant patients).
- Individuals with silicosis, a lung disease.
- People who abuse alcohol.
- Intravenous drug abusers.
- People who are homeless.

Demographics

The number of reported TB cases in the United States peaked in 1993 and has since declined. The total in 1993 was more than 25,000, compared to fewer than 9,600 in 2013, according to the Centers for Disease Control and Prevention (CDC). TB is a much greater

EDWARD LIVINGSTON TRUDEAU (1848–1915)



Edward Trudeau *(The Library of Congress.)*

Edward Livingston Trudeau (1848–1915) was an American pioneer in the treatment of tuberculosis.

Trudeau was born in New York City, the son of a physician. He began his studies at the Naval Academy but soon left to care for his ill brother, who had contracted tuberculosis and soon died. This event made Trudeau turn his attention to medicine. He attended medical school at Columbia University and became a practicing physician.

Soon Trudeau discovered that he too was infected with tuberculosis. He traveled to the Adirondack Mountains in Upstate New York, where he had visited as a child. He arrived so ill that he had to be carried to his lodging on a stretcher. Although he was weak and emaciated, he soon began to regain his health.

During the late 1800s, about one in seven individuals died of tuberculosis. The disease spread quickly through the damp, poorly ventilated slums that housed many urban poor and recent immigrants. Trudeau realized that if he had regained his health in the fresh air of the Adirondacks, so might other individuals with tuberculosis. He opened a sanatorium to provide care for infected individuals, especially those who could not afford expensive rest cures offered elsewhere.

Although the clean mountain air could help individuals with tuberculosis live longer, it did not provide a cure. In an attempt to find a cure, Trudeau learned how to culture *Mycobacterium tuberculosis* (MTb), the bacterium that causes the disease. Then he experimented to determine if the cold, damp living conditions of the poor were enough to cause the disease or whether the presence of MTb was required. To explore this question, he conducted an experiment on three groups of five rabbits. One group he injected with MTb and then confined to small, damp cages with little food. Another group he did not inject with MTb but also confined to similarly small, damp, dark quarters with a minimum of food. The third group he injected with MTb then released into the wild on a small island.

All but one of the first group of rabbits died within months, and the rabbit that survived was weak and emaciated. The five rabbits not injected with MTb all survived but were weak and thin. The group of rabbits allowed to roam free in clean air and sunlight were all alive and healthy, even though they had been injected with the MTb. These results strongly supported his suspicion that clean air and sunshine were critical to the good health of individuals with tuberculosis and that the presence of MTb was required for the disease.

Trudeau was a founder and the first president of the American Lung Association, which awards an annual medal bearing his name. After the introduction of antibiotics to treat tuberculosis, his heirs sold his sanatorium and used the proceeds to fund the Trudeau Institute, which continued into the early 2000s to perform research on immunity and infectious diseases.

health problem in other countries, particularly in Southeast Asia and the western Pacific regions, where more than half of all new cases of TB are reported; and in Africa, where the greatest proportion of new cases per population (280 per 100,000 population in 2013) occur, according to the World Health Organization (WHO).

WHO describes TB as "second only to HIV/AIDS as the greatest killer worldwide due to a single infectious agent," and reported the following global statistics for TB in 2013:

- 9 million people, including more than a half million children, fell ill, and 1.5 million died from the disease.
- Individuals in low- and middle-income countries made up the vast majority (more than 95%) of TB deaths.
- TB was among the top five causes of death for women aged 15-44.
- One-fourth of all HIV-related deaths were due to TB.

New multi drug-resistant strains of TB (MDR TB) have become a major **public health** concern. In

WWW.BOOKBAZ.IR

the United States, the percentage of MDR TB cases increased slightly from 86 cases in 2012 to 95 cases in 2013. Globally, WHO reported that nearly a half-million people had developed MDR-TB in 2013.

Causes and symptoms

Tuberculosis spreads by droplet infection. When a person infected with *M. tuberculosis* exhales, coughs, or sneezes, tiny droplets of fluid containing tubercle bacilli are released into the air. People in close physical contact with the infected person inhale this fine mist. Tuberculosis is not highly contagious compared to some other infectious diseases, and as a rule, close, frequent, or prolonged contact is needed to spread the TB. In fact, most people do not develop TB even when exposed to a person with active TB. Unlike many other infections, TB is not passed on by contact with a an infected individual's clothing, bed linens, dishes or cooking utensils. There is a risk during **pregnancy**: The fetus of an infected mother may contract TB by inhaling or swallowing the bacilli in the amniotic fluid.

Once a person inhales *M. tuberculosis*, one of four things can happen.

- The person's immune system can kill the bacteria; no TB infection results and the person is not contagious.
- The bacteria can become dormant and never grow; no TB symptoms are seen, and the person is not contagious.
- The bacteria can become dormant for a period, then begin to grow. Therefore, TB symptoms appear a long time after infection. The person is not contagious during the dormant period, but becomes contagious when symptoms appear.
- The bacteria multiples immediately; active TB symptoms appear and the person is contagious.

There are several types of TB, including pulmonary tuberculosis, extrapulmonary tuberculosis, and multi-drug resistant tuberculosis.

Pulmonary tuberculosis is TB that affects the lungs. Its initial symptoms are easily confused with those of other diseases. An infected person may at first feel vaguely unwell or develop a **cough** that could be blamed on **smoking** or a cold. A small amount of greenish or yellow sputum may be coughed up when the person gets up in the morning. In time, more sputum is produced that is streaked with blood. People who have pulmonary TB do not get a high **fever**, but they often have a low-grade one. The individual often loses interest in food and may lose weight. Chest **pain** is sometimes present. If the infection allows air to escape from the lungs into the chest cavity (pneumothorax) or if fluid collects in the pleural space (**pleural effusion**), the patient may have difficulty breathing. If a young adult develops a pleural effusion, it is often diagnosed as tubercular infection.

Before the development of effective TB drugs, many patients became chronically ill with increasingly severe lung symptoms. They lost a great deal of weight and developed a wasted appearance, which led to the olden term for tuberculosis: consumption. This outcome is uncommon today where modern treatment methods are available.

Typically, TB spreads from the lungs to locations outside the lungs (extrapulmonary sites). In occasional cases, the first sign of disease appears outside the lungs (extrapulmonary tuberculosis). The many tissues or organs that tuberculosis may affect include:

- Bones. TB is particularly likely to attack the spine and the ends of the long bones. If not treated, the spinal segments (vertebrae) may collapse and cause paralysis in one or both legs. Children are especially prone to spinal TB.
- Kidneys. Along with the bones, the kidneys are the most common sites of extrapulmonary TB. TB may also spread to the bladder, and in men, to the prostate gland and nearby structures.
- Female reproductive organs, including the ovaries. TB may spread from the ovaries to the peritoneum (the membrane lining the abdominal cavity).
- Abdominal cavity. Tuberculosis peritonitis may cause pain ranging from the vague discomfort of stomach cramps to intense pain that may mimic the symptoms of appendicitis.
- Joints. Tubercular infection of joints causes a form of arthritis that most often affects the hips and knees. The wrist, hand, and elbow joints also may become painful and inflamed.
- Meninges. Infection of the meninges (tissues that cover the brain and the spinal cord) causes tuberculosis meningitis, a condition that is most common in young children but is especially dangerous in the elderly. Patients develop headaches, become drowsy, and eventually, comatose. Permanent brain damage is the rule unless prompt treatment is given. Some patients with tuberculosis meningitis develop a tumor-like brain mass called a tuberculoma that can cause stroke-like symptoms.
- Skin, intestines, adrenal glands, and blood vessels. Infection of the wall of the body's main artery (the aorta), can cause it to rupture with catastrophic results. Tuberculosis pericarditis occurs when the

membrane surrounding the heart (the pericardium) is infected and fills up with fluid that interferes with the heart's ability to pump blood.

- Miliary tuberculosis. This is a life-threatening condition that occurs when large numbers of tubercle bacilli spread throughout the body, and huge numbers of tiny tubercular lesions develop that cause marked weakness and weight loss, severe anemia, and gradual wasting of the body.

There is increasing concern about strains of *M. tuberculosis* that are resistant to the TB drugs that have brought the disease under control in the past. MDR TB is TB that fails to respond to at least two drugs, isoniazid (INH) and rifampin (RIF), that are routinely used to treat TB. In the United States, MDR TB, although rare, is on the rise. The CDC has developed a special group of experts to work with physicians who have MDR TB patients. There is concern that drug-resistant TB could spread widely and cause a public health crisis.

There are many forms of mycobacteria, and some cause infections that may closely resemble tuberculosis, but they usually do so only when an infected person's immune system is defective.

Diagnosis

The standard screening test for tuberculosis is the **tuberculin skin test**. This test detects the presence of infection, not of active TB. Tuberculin is an extract prepared from cultures of *M. tuberculosis*. It contains proteins belonging to the bacillus (antigens) to which an infected person has been sensitized. When tuberculin is injected into the skin of an infected person, the area around the injection becomes hard, swollen, and red within one to three days.

To verify the test results, the physician will do a chest x ray and obtain a sample of sputum or a tissue sample (biopsy) for culture, which is used to identify *M. tuberculosis*.

If TB has invaded the brain or spinal cord, culturing a sample of spinal fluid will make the diagnosis. If TB of the kidneys is suspected because of pus or blood in the urine, culture of the urine may reveal tubercular infection. Infection of the ovaries in women can be detected by inserting a tube having a light on its end (a laparoscope) into the area. Samples also may be taken from the liver or bone marrow to detect the tubercle bacillus.

For most people, a simple skin test is adequate to screen for TB. However, new advances in the diagnosis of TB use molecular techniques to speed the diagnostic process as well as improve its accuracy. Blood tests using advanced technology are used to measure the patient's immune reaction to TB bacteria.

Treatment

Most patients with TB recover if given appropriate medication for a sufficient length of time. Three principles govern modern drug treatment of TB.

- Lowering the number of bacilli as quickly as possible, which minimizes the risk of transmitting the disease.
- Preventing the development of drug resistance. For this reason, at least two different drugs and sometimes up to four are given as initial treatment.
- Long-term treatment to prevent relapse.

Five drugs are most commonly used treat tuberculosis: isoniazid (INH, Laniazid, Nydrazid), rifampin (Rifadin, Rimactane), pyrazinamide (Tebrazid), streptomycin, and ethambutol (Myambutol). The combinations vary by the patient's needs.

Except in cases of MDR TB, prolonged hospitalization is rarely necessary because most patients are no longer infectious after about two weeks of combination treatment. Follow-up involves monitoring of side effects and monthly sputum tests. Of the five medications, INH is the most frequently used drug for both treatment and prevention. Hospitalization, **isolation**, and infectious control measures are required for individuals with MDR TB, which is a very serious disease both for the individual and from a public health standpoint. Most states have laws that allow individuals with TB to be hospitalized against their will for noncompliance with treatment.

Surgical treatment of TB is rarely used. Doctors may recommend surgery for patients whose disease cannot be controlled by disease, or who encounter complications in the lungs or another part of the body. The surgery may be used to remove a bacterial site in the lungs, remove or repair damage to the lungs or other organs, or to treat rare complications stemming from infection to the brain, heart, kidneys, or joints.

Prognosis

Most patients recover from TB if the disease is diagnosed early and they receive prompt treatment with appropriate medications on a long-term regimen. When TB is multi drug-resistant, the prognosis depends largely on the ability to surgically remove all infected tissue. The outcome of surgery depends on where and how widespread the infected area is. Miliary tuberculosis is still fatal in many cases but is rarely seen today in developed countries.

KEY TERMS

Bacillus Calmette-Guérin (BCG)—A vaccine made from a weakened bacillus similar to the tubercle bacillus, which may help prevent serious pulmonary TB and its complications.

Mantoux test—Another name for the PPD test.

Miliary tuberculosis—The form of TB in which the bacillus spreads through all body tissues and organs, producing many thousands of tiny tubercular lesions. Miliary TB is often fatal unless promptly treated.

Mycobacteria—A group of bacteria that includes *Mycobacterium tuberculosis*, the bacterium that causes tuberculosis, and other forms that cause related illnesses.

Pneumothorax—Air inside the chest cavity, which may cause the lung to collapse. Pneumothorax is both a complication of pulmonary tuberculosis and a means of treatment designed to allow an infected lung to rest and heal.

Purified protein derivative (PPD)—An extract of tubercle bacilli that is injected into the skin to find out whether a person presently has or has ever had tuberculosis.

Sputum—Secretions produced in the lung and coughed up. A sign of illness, sputum is routinely used as a specimen for culturing the tubercle bacillus in the laboratory.

Tuberculoma—A tumor-like mass in the brain that sometimes develops as a complication of tuberculosis meningitis.

Prevention

General measures such as avoidance of overcrowded and unsanitary conditions are one aspect of prevention. Regular skin testing is required in some jobs and of most children when they enter school and often again if when enter college. Although screening does not prevent TB, it allows early treatment of those who are infected, reducing the likelihood that they will spread the disease.

Vaccination is a preventive measure against TB. A vaccine called BCG (Bacillus Calmette–Guérin, named after its French developers) is made from a weakened mycobacterium that infects cattle. Vaccination with BCG does not prevent infection by *M. tuberculosis*, but it does strengthen the immune system response and provide partial protection. BCG is widely used in developing countries that have a high prevalence of TB to prevent some forms of TB, but it is generally not recommended or used in the United States.

A new TB vaccine, known as modified Vaccinia Ankara virus expressing antigen 85A (MVA85A), was designed to work with and improve upon BCG, which is not completely effective in preventing TB. Developed at Oxford University, England, in response to increasing concern about the rise of MDR TB, trials to test its safety and efficacy continue as of 2014.

INH can be given for the prevention as well as the treatment of TB. INH is given daily over a period of six to nine months to people in high-risk categories or who have latent TB infection. INH carries the risk of side effects (liver inflammation, nerve damage, changes in mood and behavior) in about one-fifth of people taking the drug.

Tularemia

Definition

Tularemia is an illness caused by a bacterium. It results in **fever**, rash, and greatly enlarged lymph nodes.

Description

Tularemia infects a variety of wild animals, including rabbits, deer, squirrels, muskrat, and beaver. Humans can acquire the bacterium directly from contact with the blood or body fluids of these animals, from the bite of a tick or fly that has previously fed on the blood of an infected animal, or from contaminated food or water.

Tularemia occurs most often in the summer months. It is most likely to infect people who come into contact with infected animals, including hunters, furriers, butchers, laboratory workers, game wardens, and veterinarians. In the United States, the vast majority of cases of tularemia occur in the southeastern and Rocky Mountain states.

Causes and symptoms

Five types of illness may occur, depending on where/how the bacteria enter the body:

- Ulceroglandular/glandular tularemia. Seventy-five to 85% of all cases are of this type. This type is contracted through the bite of an infected tick that has defecated bacteria-laden feces in the area of the bite wound. A tender red bump appears in the area of the original wound. Over a few weeks, the bump develops a punched-out center (ulcer). Nearby lymph nodes grow hugely swollen and very tender. The lymph nodes may drain a thick, pus-like material. Other symptoms include fever, chills, and weakness. In adults, the lymph nodes in the groin are most commonly affected; in children, the lymph nodes in the neck.
- Oculoglandular tularemia. This type accounts for only about 1% of all cases of tularemia. It occurs when a person's contaminated hand rubs his or her eye. The lining of the eyelids and the surface of the white of the eye (conjunctiva) becomes red and severely painful, with multiple small yellow bumps and pitted sores (ulcers). Lymph nodes around the ears, under the jaw, or in the neck may swell and become painful.
- Oropharyngeal and gastrointestinal tularemia. This type occurs when contaminated meat is undercooked and then eaten, or when water from a contaminated source is drunk. Poor hygiene after skinning and cleaning an animal obtained through hunting can also lead to the bacteria entering through the mouth. Sores in the mouth and throat, as well as abdominal pain, nausea and vomiting, ulcers in the intestine, intestinal bleeding, and diarrhea may all occur.
- Pulmonary tularemia. This rare type of tularemia occurs when a person inhales a spray of infected

KEY TERMS

Shock—A state in which drastically low blood pressure prevents adequate blood flow to the tissues and organs throughout the body.

fluid, or when the bacteria reach the lungs through the blood circulation. A severe pneumonia follows.

- Typhoidal tularemia. This type of tularemia is particularly hard to diagnose, because it occurs without the usual skin manifestations or swelling of lymph glands. Symptoms include continuously high fever, terrible headache, and confusion. The illness may result in a severely low blood pressure, with signs of poor blood flow to the major organs (shock).

Diagnosis

Samples from the **skin lesions** can be prepared with special stains, to allow identification of the causative bacteria under the microscope. Other tests are available to demonstrate the presence of antibodies (special immune cells that the body produces in response to the presence of specific foreign invaders) that would be increasing over time in an infection with tularemia.

Treatment

Streptomycin (given as a shot in a muscle) and gentamicin (given as either a shot in a muscle or through a needle in the vein) are both used to treat tularemia. Other types of **antibiotics** have been tested, but have often resulted in relatively high rates of relapse (20%).

Prognosis

With treatment, death rates from tularemia are under 1%. Without treatment the death rate may reach 30%. The **pneumonia** and typhoidal types have the worst prognosis without treatment.

Prevention

Prevention involves avoiding areas known to harbor ticks and flies, or the appropriate use of insect repellents. Hunters should wear gloves when skinning animals or preparing meat. Others (butchers, game wardens, veterinarians) who work with animals or carcasses should always wear gloves. A vaccine exists, but is usually only given to people at very high risk due to their profession or hobby (veterinarians, laboratory workers, butchers, hunters, game wardens).

Tumor markers

Definition

Tumor markers are measurable biochemicals that are associated with a malignancy. They are either produced by tumor cells (tumor-derived) or by the body in response to tumor cells (tumor-associated). They are typically substances that are released into the circulation and thus measured in the blood. There are a few exceptions to this, such as tissue-bound receptors that must be measured in a biopsy from the solid tumor or proteins that are secreted into the urine.

Purpose

Though tumor markers are rarely specific enough to be used alone to diagnose cancer, they do have a number of clinical uses. They can be used to stage cancer, to indicate a prognosis, to monitor treatment, or in follow-up to watch for cancer recurrence. Changes in some tumor markers have been sensitive enough to be used as targets in clinical trials. When used for diagnosis, tumor markers are used in conjunction with other clinical parameters such as biopsy and radiological findings. Although there are a multitude of tumor markers, very few of them have found their way into clinical practice because of their lack of specificity. However, some of these non-specific markers have found a place in monitoring cancer treatment rather than in diagnosis.

Description

As tumor cells grow and multiply, some of their substances can increase and leak into the bloodstream or other fluids. Depending upon the tumor marker, it can be measured in blood, urine, stool or tissue. Some widely used tumor markers include: AFP, beta-HCG, CA 15-3, CA 19-9, CA 27-29, CA 125, CEA, and PSA. Some tumor markers are associated with many types of cancer; others, with as few as one. Some tumor markers are always elevated in specific cancers; most

are less predictable. However, no tumor marker is specific for cancer and most are found in low levels in healthy persons, or can be associated with non-neoplastic diseases as well as cancer. Also, no tumor marker test is free of false negatives or false positives.

Once cancer is diagnosed, tumor marker levels sometimes help to determine the extent of cancer. Higher levels can indicate more advanced cancer and a worse prognosis in some cases. Patients and their physician may use this information to choose between more or less aggressive treatments.

Monitoring cancer treatment is the most common use of tumor markers. As cancer is reduced, levels often decrease. Stable or increasing levels often indicate that the cancer is not responding to treatment. The choice of tumor marker to use for monitoring is important. Only a marker elevated before treatment should be used to monitor a person during or after treatment. Timing of the tests is also important. Each tumor marker has a unique life span in the blood. To monitor a treatment's success, enough time must have passed for the initial marker to be cleared from the blood. Tests done too soon may be falsely elevated because the marker produced by the untreated cancer is still present.

Watching for cancer recurrence after treatment is another reason for tumor marker testing. Periodic testing can sometimes detect a recurrence often months earlier than could an **ultrasound**, x ray, or **physical examination**.

Tumor marker tests are performed in a lab using immunological techniques. A sample of blood or other tissue is mixed with a substance containing specific antibodies to each tumor marker. If that tumor marker is present, these very specific antibodies bind to the markers. Some type of label, often a radioactive substance, is then used to measure the amount of bound marker and antibody. From this measurement, the amount of tumor marker is calculated. The results are usually available within a few days.

Conclusions based on tumor marker tests are seldom based on one test result but on a series of test results, called serial measurements. A series of increasing or decreasing values is more significant than a single value.

Tumor marker testing is currently the object of much research and attention. Their use is directed by approval from the Food and Drug Administration (FDA) and guidelines established by organizations such as the American Society of Clinical Oncology and the American Cancer Society. Not all tumor receptor marker tests are widely available nor are they widely accepted.

Oncofetal antigens

There are two common oncofetal antigens, alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA). Carcinoembryonic antigen CA 72-4 is a more recently discovered oncofetal antigen just coming into usage. The oncofetal antigens are so named because they are normally produced during embryonic development and decrease soon after birth. Cancer cells tend to dedifferentiate, or revert to a more immature tissue and begin to produce fetal antigens again. Oncofetal antigens are very non-specific and expressed by a wide number of cancer types. They are used both to monitor a patient's progress and their response to treatment over time.

ALPHA-FETOPROTEIN (AFP). Elevated AFP typically indicates a primary liver tumor or a germ cell tumor of the ovary or testicle. AFP is a glycoprotein produced in high amounts by fetal tissue and is elevated during **pregnancy**. It is most widely used as a marker for hepatocellular carcinoma and **testicular cancer** but is also associated with **ovarian cancer**. Seventy percent of people with **liver cancer** have increased AFP levels. In China, where liver cancer rates are high, AFP is used as a screening test for that disease. AFP levels indicate the extent of cancer, and serial measurements are used to monitor treatment response. Non-cancerous liver conditions such as **cirrhosis** and hepatitis have moderately increased levels of AFP.

CARCINOEMBRYONIC ANTIGEN (CEA). CEA is a glycoprotein most often associated with colorectal cancer, and used to monitor patients with this type of cancer. Its most popular use is in early detection of relapse in individuals already treated for colorectal cancer. After surgery, serial measurements indicate the surgery's success and are used to detect early signs of recurrence. It has recently been found to be useful when measured during surgery for colorectal cancer to help determine prognosis and who will benefit from adjuvant treatment.

CEA is measured in the blood plasma. It is very non-specific and can be increased in many types of cancer: gastrointestinal, colorectal, ovarian, bladder, cervical, stomach, kidney, lung, pancreatic, liver, prostate, thyroid, **melanoma**, lymphoma, and breast. People with noncancerous conditions, such as cirrhosis or peptic disease, or inflammatory intestinal conditions such as **colitis** or **diverticulitis**, may also have increased levels. CEA levels can be elevated in elderly patients and in those who smoke.

CANCER ANTIGEN 72-4 (CA 72-4). The more recently identified carcinoembryonic protein is CA 72-4. Although it is slightly elevated with most carcinomas,

WWW.BOOKBAZ.IR

it is mostly associated with gastric carcinoma (**stomach cancer**). CA 74-2 is finding a role in the management of patients with gastric carcinoma.

Cancer antigen 15-3 (CA 15-3)

CA 15-3 is produced by cells in the breast and increased levels can be associated with **breast cancer**. Rarely increased in women with early breast cancer, it may be used to detect recurrence of cancer in women following treatment or **mastectomy** and to monitor treatment for women with advanced breast cancer. However, adenocarcinomas of the ovary, lung, colon, and pancreas also express elevated CA 15-3 levels. Non-cancerous conditions sometimes associated with elevated CA 15-3 include benign breast or ovarian disease, **endometriosis**, **pelvic inflammatory disease**, and hepatitis. Pregnancy and **lactation** are also related to high CA 15-3 levels.

Cancer antigen 27-29 (CA 27-29)

CA 27-29, also called breast carcinoma-associated antigen, is used as a marker for breast cancer. Eighty percent of women with breast cancer have an increased CA 27-29 level. This marker may be used with other procedures and tumor marker levels such as CA 15-3 to check for recurrences of cancer in previously treated women. Serial measurements monitor treatment response and identify recurrence.

Levels of CA 27-29 may also be increased in cancers of the colon, stomach, kidney, lung, ovary, pancreas, uterus, and liver. Noncancerous conditions associated with elevated CA 27-29 include first trimester pregnancy, endometriosis, **ovarian cysts**, non-cancerous breast disease, **kidney disease**, and **liver disease**.

HER-2/neu

HER-2/neu is an oncogenic growth factor receptor also known as c-erbB-2. It is measured in the tissue from a biopsy either by immunological assays of the protein or polymerase chain reaction (PCR) to identify the DNA. The presence of HER-2/neu is generally associated with a poorer prognosis for breast cancer. It can also help to determine treatment options, since newer drugs can block this protein and decrease cancer growth. The most widely known of these drugs is trastuzumab (Herceptin).

Estrogen receptor

Measurement of the estrogen receptor (ER) is used specifically to evaluate breast cancers. It gives an indication of prognosis and responsiveness to therapy. Tissue from a biopsy is used to measure the estrogen receptor. Most breast cancers in post-menopausal women are ER-positive, meaning that they require estrogen to grow. These ER positive breast cancers are less aggressive than ER negative breast cancers, which are found generally in pre-menopausal women.

Cancer antigen 125 (CA 125)

Although produced by a number of cell types, CA 125 is primarily produced by ovarian cancer cells. Eighty percent of women with ovarian cancer have increased CA 125 levels. Although the test is not sensitive or specific enough to be used for screening, it contributes to a diagnosis when combined with an ultrasound and pelvic examination. Blood levels of CA 125 are used primarily to monitor the treatment of ovarian cancer. A falling CA 125 level usually indicates that cancer is responding to the treatment. After diagnosis and treatment, serial measurements help detect remaining or recurrent cancer. A negative or normal result, however, does not guarantee the absence of cancer.

Women may have increased CA 125 levels during menstruation and pregnancy. Increased levels are also found in pelvic inflammatory disease, endometriosis, **pancreatitis**, and liver disease. Elevated levels are associated with non-ovarian cancers including cancers of the uterus, cervix, pancreas, liver, colon, breast, lung, or digestive tract.

Prostate specific antigen (PSA)

Prostate specific antigen (PSA) levels, along with the **digital rectal examination**, are used to screen for **prostate cancer**. PSA is a protein produced by the prostate gland and can be overproduced in prostate cancer. It is perhaps the best tumor marker in use because of its tissue specificity, meaning that it is produced only by the prostate. Men over the age of 50 are advised to consider annual screening for prostate cancer. Men at high risk for prostate cancer, such as African Americans or those with a family history of the disease, should begin screening at age 40. Once a diagnosis of prostate cancer is made, PSA levels can help determine the stage of the cancer, monitor the response to treatment, and watch for recurrence.

Measurements of PSA following **prostatectomy** are useful in determining the success of surgery. Any PSA level following surgery would indicate residual prostate tissue, possibly from metastasis. PSA levels can also be used to detect a recurrence of prostate cancer. PSA is also increased in benign prostatic hyperplasia (BPH), an **enlarged prostate** condition common in older men.

PSA can be found in the serum in two states, bound and free. Measuring both PSA levels can provide more specificity to the test and reduce unnecessary biopsies. The percentage of free PSA is greater in BPH than prostate cancer. If the total PSA level is higher than 4.0 nanogram/milliliter (ng/mL) and the free PSA level is less than 25%, a **prostate biopsy** is indicated.

PSA levels may increase after ejaculation. Men are recommended to abstain from sexual intercourse or masturbation for 48 hours before the test. PSA levels may also increase after prostate manipulation following the digital rectal exam.

Prostatic acid phosphatase (PAP) was originally found to be produced by the prostate and thought to be a marker for prostate cancer. It is now found to be elevated with testicular cancer, leukemia, non-Hodgkin's lymphoma and several noncancerous conditions.

Cancer antigen 19-9 (CA 19-9)

CA 19-9 has been identified in patients with digestive tract or intra-abdominal carcinomas such as colorectal cancer, pancreatic cancer, stomach cancer and **bile duct cancer**. In pancreatic cancer, higher levels are associated with more advanced disease. After diagnosis, levels help predict the success of surgery and monitor the course of the cancer. Not all people with pancreatic cancer have increased CA 19-9 levels. This antigen is related to the Lewis blood group and so only patients positive for the Lewis blood group antigen will test positive for CA 19-9. It is also increased in liver and gastrointestinal cancers and in noncancerous diseases, including pancreatitis, **gallstones** and **jaundice**.

Human chorionic gonadotropin (hCG)

Human chorionic gonadotropin is normally produced by the placenta during pregnancy. There are two protein subunits that make up HCG, beta and alpha. It is the beta subunit that is increased in women's serum during early pregnancy. It is also the beta subunit that is increased in some malignant tumors. Tumors that secrete beta-hCG are typically **germ cell tumors** such as teratocarcinomas. These are tumors found in the ovaries and testes that contain embryonal tissue. Rarely, these types of tumors are found in the pineal region of the brain where beta-hCG can serve as a marker. Levels of hCG rise with **choriocarcinoma** and with trophoblastic disease, a rare cancer that develops from an abnormally fertilized egg. Gestational trophoblastic tumors also secrete AFP and this test is often used in combination.

HCG is most often used to screen for cancer of the testis or ovary. Serial measurements monitor the progress and treatment of these cancers. This marker can be elevated in individuals who use **marijuana**.

Squamous cell carcinoma (SCC) Antigen

Squamous cell carcinoma (SCC) antigen was first identified in **cervical cancer**. It is a marker for squamous cell cancers, which can occur in the cervix, head and neck, lung, and skin. Levels of SCC can be used as an aid to stage the carcinoma and to determine the response to treatment.

Bence-Jones protein

Patients with plasmacytomas such as myeloma overproduce monoclonal immunoglobulins, also called M proteins. The Bence-Jones protein refers to the immunoglobulin light chain, a portion of these immunoglobulins. The Bence-Jones protein is secreted into the urine where it can be measured. It was the first tumor marker identified.

Neuron-specific enolase (NSE)

NSE is a protein found mainly in neurons and neuroendocrine cells. It is elevated in tumors derived from these tissues, including **neuroblastoma** and **small cell lung cancer**. It can give information about the extent of the disease, the patient's prognosis and the patient's response to treatment. NSE can also be elevated in medullary thyroid cancers, carcinoid tumors, pancreatic endocrine tumors, and melanoma.

Hormone assays

Tumors of the endocrine glands oversecrete their corresponding hormones. By measuring particular hormones, clues can be obtained regarding certain cancers. For instance, breast cancer cells may secrete prolactin and estrogen. Medullary carcinoma can secrete calcitonin. Pheochromocytomas secrete catecholamines. Tumors of the pituitary gland may secrete growth hormone or cortisol. Carcinoid tumors secrete serotonin. Some tumors of the pancreas secrete insulin. Serial measurements can also monitor treatment for these tumors.

Enzymes

Several serum enzymes can be measured to help detect metastases in cancer patients. Tumors that metastasize to the liver cause increases in serum alkaline phosphatase, gamma-glutamyltransferase, and transaminases. Although these are not necessarily tumor markers, they indicate liver damage that may

WWW.BOOKBAZ.IR

be caused by metastatic cancer. Tumors that metastasize to the bone sometimes secrete elevated alkaline phosphatase. Lactate dehydrogenase is an enzyme found throughout the body. Because of this it cannot be used as a marker for cancer. It can, however, be used to monitor the treatment of some types of cancer including germ cell tumors, testicular cancer, Ewing's sarcoma, non-Hodgkins lymphoma and some types of leukemia.

Precautions

There is not a good consensus in the medical community about the value of most tumor markers. Because they lack specificity and accuracy, their use is limited. False positives can cause emotional distress and fear. It is not yet determined if there is a savings of life or money with testing. Much controversy surrounds the issue of mass screening for cancer using tumor markers.

Preparation

Tumor marker tests usually require 5-10 mL of blood. A healthcare worker ties a tourniquet on the patient's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes a few minutes and results are available within a few days.

Some markers, such as those for **bladder cancer**, **multiple myeloma**, and plasmacytomas, are measured in the urine. Typically this requires a 24-hour urine sample, which means that the individual must collect all of his or her urine for 24 hours. This is usually about 1.5 L or more. These results are then available within a few days.

Other tumor markers require tissue samples for analysis. These include receptor analysis such as estrogen receptor and Her-2/neu. Tissue samples are obtained by biopsy. This is usually done by inserting a needle through the skin and into the tumor. The area is typically numbed prior to the procedure. These results are also available within two to three days.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort. There is a rare chance of infection occurring especially after biopsy. Any sign of infections should be watched for such as **pain** and redness.

Results

- AFP: 99% of (nonpregnant) people have less than 15 ng/mL; 95% have less than 6 ng/mL. Serum AFP levels higher than 400 micrograms/L are associated with cancer or some other pathology.
- Beta-HCG: in males, less than 2.5 IU/L; in females, less than 5.0 IU/L; in postmenopausal females, less than 9.0 IU/L.
- CA 15-3: less than 40 U/mL.
- CA 19-9: less than 40 U/mL.

- CA 27.29: less than or equal to 38 U/mL.
- CA 125: less than 35 U/L.
- CEA: less than or equal to 5 ng/mL.
- PSA: less than 4 ng/mL; PSA levels increase with age. Age-specific values range from 2.0 micrograms/L at age 40 to 7.2 micrograms/L at age 80. Typically, levels below 4.0 micrograms/L rule out prostate cancer.

Abnormal results

The meaning of an increased tumor marker level depends on the specific marker, the person's medical history, and why the test was done. Knowledge of the patient's history and additional tests and physical examinations are needed to correctly interpret tumor marker test results.

Tumor necrosis factor

Definition

Tumor necrosis factor is a protein produced by several of the body's cell types, such as white blood cells, red blood cells, and other cells that line the blood vessels. It promotes the destruction of some types of cancer cells.

Description

In the 1970s, researchers took sarcoma cells in culture and exposed them to a protein produced by white blood cells. The protein caused necrosis (death) of the sarcoma cells but had little effect on normal cells in the culture. Hence, the protein was called tumor necrosis factor (TNF).

TNF is a type of cytokine released by white blood cells. Cytokines are a group of protein molecules that are released by many different cells to communicate with other cells and regulate the duration of an immune response. There are many different kinds of cytokines, each with a different effect on specific target cells. Once a cell releases the cytokines, they bind to corresponding receptors located on target cells, thus causing a change to take place within the target cell. Tumor necrosis factor is released by special white blood cells called macrophages. Although researchers are still investigating the exact mechanism by which TNF kills cancer cells, it is clear that TNF binds to receptors located on the surface of cancer cells, causing a change and then death of the cell. This was found to be true in animal models. As a result, researchers thought TNF might enhance the reaction of the human immune system to cancer cells.

In the mid-1980s, TNF became available in recombinant form and was analyzed in clinical human trials. Recombinant means that it was genetically engineered, or made in a laboratory. At that time, researchers discovered that TNF administered systemically was toxic to humans' normal tissues at the maximum doses required to kill all of the cancer cells, thus limiting its usefulness. At maximum doses required to kill cancer cells, patients experienced **fever**, loss of appetite

WWW.BOOKBAZ.IR

(anorexia), and cachexia (severe weight loss, **malnutrition**, and wasting away of the body).

However, TNF can be effectively combined with other systemic chemotherapeutic drugs such as doxorubicin and etoposide. TNF in conjunction with these drugs enhances DNA breakage in tumor cells, contributing to their death. In addition to administering TNF systemically, TNF (with or without other chemotherapeutic drugs) can be forced through the blood at the capillary beds at or near the site of the tumor. The regional perfusion of TNF allows larger dosages to be administered only in the area requiring the treatment. Therefore, less normal and healthy tissue is disrupted before reaching the maximum tolerable limits. Research performed in 1998 (by Lejeune, et al.) found regional perfusion to be especially successful in the case of **melanoma** metastasis, resulting in complete remission of 70–80% of patients.

TNF also is used to treat forms of arthritis, gastrointestinal diseases, **psoriasis**, and other conditions.

Although TNF is valuable in killing cells in melanoma and sarcoma tumors, it can promote growth of other kinds of cancers. In April 2011, the U.S. Food and Drug Administration (FDA) issued a special warning regarding use of TNF blockers. An increasing number of children and adolescents receiving TNF blockers for treatment of ulcerative **colitis** and Crohn's disease were reported to be developing a rare cancer of white blood cells called hepatosplenic T-cell lymphoma. As of 2014, the FDA continued to warn extra vigilance among doctors who use the drugs to treat children and young adults because of the increased cancer risk.

Tumor removal

Definition

A tumor is an abnormal growth in the body that is caused by the uncontrolled division of cells. Benign tumors do not have the potential to spread to other parts of the body (a process called metastasis) and are curable by surgical removal. Malignant or cancerous tumors, however, may metastasize to other parts of the body and will ultimately result in death if not successfully treated by surgery and/or other methods.

Purpose

Surgical removal is one of four main ways that tumors are treated; the other treatment options include **chemotherapy**, **radiation therapy**, and biological therapy. There are a number of factors used to determine which methods will best treat a tumor. Because benign tumors do not have the potential to metastasize, they are often treated successfully with surgical removal alone. Malignant tumors are most often treated with a combination of surgery and chemotherapy and/or radiation therapy (in about 55% of cases). In some instances, non-curative surgery may make other treatments more effective. Debulking a cancer—making it smaller by surgical removal of a

large part of it—is thought to make radiation and chemotherapy more effective.

Surgery is often used to accurately assess the nature and extent of a cancer. Most cancers cannot be adequately identified without examining a sample of the abnormal tissue under a microscope. Such tissue samples are procured during a surgical procedure. Surgery may also be used to determine exactly how far a tumor has spread and to establish its margins.

There are a few standard methods of comparing one cancer to another for the purposes of determining appropriate treatments and estimating outcomes. These methods are referred to as staging. The most commonly used method is the TNM system:

- **T** stands for tumor, and reflects the size of the tumor.
- **N** represents the spread of the cancer to lymph nodes, largely determined by those nodes removed at surgery that contain cancer cells. Since cancers spread mostly through the lymphatic system, this is a useful measure of a cancer's ability to disperse.
- **M** refers to metastasis, and indicates if metastases are present and how far they are from the original cancer.

KEY TERMS

Aspiration—A technique for obtaining a piece of tissue for biopsy by using suction applied through a needle attached to a syringe.

Biopsy—The removal of living tissue from the body, done in order to establish a diagnosis.

Debulking—Surgical removal of a major portion of a tumor less of the cancer is left for later treatment by chemotherapy or radiation.

Mammogram—A set of x rays taken of the front and side of the breast; used to diagnose various abnormalities of the breast.

Metastasis (plural, metastases)—A growth of cancer cells at a site in the body distant from the primary tumor.

Oncologist—A physician who specializes in the diagnosis and treatment of tumors.

Palliative—Offering relief of symptoms, but not a cure.

Pap test—The common term for the Papanicolaou test, a simple smear method of examining stained cells to detect cancer of the cervix.

Staging—The classification of cancerous tumors according to the extent of the tumor.

Staging is particularly important with such lymphomas as Hodgkin's disease, which may appear in many places in the lymphatic system. Surgery is a useful tool for staging such cancers and can increase the chance of a successful cure, since radiation treatment is often curative if all the cancerous sites are located and irradiated.

Demographics

The American Cancer Society estimates that approximately 1,660,290 cases of cancer were diagnosed in the United States in 2013. Seventy-eight percent of cancers are diagnosed in men and women over the age of 55, although cancer may affect individuals of any age. Men develop cancer more often than women; one in two men will be diagnosed with cancer during his lifetime, compared to one in three women. Additionally, men are more likely to die of cancer. Cancer affects individuals of all races and ethnicities, although incidence may differ among these groups by cancer type.

Description

Surgery may be used to remove tumors for diagnostic or therapeutic purposes.

Diagnostic tumor removal

A biopsy is a medical procedure that obtains a small piece of tissue for diagnostic testing. The sample is examined under a microscope by a doctor who specializes in the effects of disease on body tissues (a pathologist) to detect any abnormalities. A definitive diagnosis of cancer cannot be made unless a sample of the abnormal tissue is examined histologically (under a microscope).

There are four main biopsy techniques used to diagnose cancer:

- In an aspiration biopsy, a needle is inserted into the tumor and a sample is withdrawn. This procedure may be performed under local anesthesia or with no anesthesia at all.
- For a needle biopsy, a special cutting needle is inserted into the core of the tumor and a core sample is cut out. Local anesthesia is most often administered.
- With an incisional biopsy, a portion of a large tumor is removed, usually under local anesthesia in an outpatient setting.
- In an excisional biopsy, an entire cancerous lesion is removed along with surrounding normal tissue (called a clear margin). Local or general anesthesia may be used.

Therapeutic tumor removal

Once surgical removal has been decided, a surgical oncologist will remove the entire tumor, taking with it a large section of the surrounding normal tissue. The healthy tissue is removed to minimize the risk that abnormal tissue is left behind. Tumors may be removed by cutting with steel instruments, use of a laser beam, radiofrequency ablation (the use of radiofrequency energy to destroy tissue), cryoablation (the use of extreme cold to freeze and thus destroy the tumor), or by injecting alcohol into the tumor.

When surgical removal of a tumor is unacceptable as a sole treatment, a portion of the tumor is removed to debulk the mass; this process is called cytoreduction. Cytoreductive surgery aids radiation and chemotherapy treatments by increasing the sensitivity of the tumor and decreasing the number of necessary treatment cycles.

Certain types of skin tumors can be removed by a technique called Mohs micrographic surgery, developed

in the late 1930s by Dr. Frederick E. Mohs. The Mohs method involves four steps: surgical removal of the tumor, making a slide of the removed tissue and examining it for cancer cells (called mapping the tissue), interpreting the microscope slides and removing more tissue if necessary until no more cancer cells are found, and performing **reconstructive surgery** to cover the wound.

A newer technique for removing some tumors of the spinal cord involves the use of a suction tip rather than a scalpel. The newer technique appears to have a wider margin of safety when working around the delicate structures of the central nervous system.

In some instances, the purpose of tumor removal is not to cure the cancer, but to relieve the symptoms of a patient who cannot be cured. This approach is called palliative surgery. For example, a patient with advanced cancer may have a tumor causing significant **pain** or bleeding; in such a case, the tumor may be removed to ease the patient's pain or other symptoms even though a cure is not possible.

Seeding

The surgical removal of malignant tumors demands special considerations. There is a danger of spreading cancerous cells during the process of removing abnormal tissue (called seeding). Presuming that cancer cells can implant elsewhere in the body, the surgeon must minimize the dissemination of cells throughout the operating field or into the bloodstream.

Special techniques called block resection and no-touch are used. Block resection involves taking the entire specimen out as a single piece. The no-touch technique involves removing a specimen by handling only the normal tissue surrounding it; the cancer itself is never touched. These approaches prevent the spread of cancer cells into the general circulation. The surgeon takes great care to clamp off the blood supply first, preventing cells from leaving by that route later in the surgery.

Diagnosis

A tumor may first be palpated (felt) by the patient or by a healthcare professional during a **physical examination**. A tumor may be visible on the skin or protrude outward from the body. Still other tumors are not evident until their presence begins to cause such symptoms as weight loss, **fatigue**, or pain. In some instances, tumors are located during routine tests (e.g., a yearly mammogram or Pap smear).

Aftercare

Retesting and periodical examinations are necessary to ensure that a tumor has not returned or metastasized after total removal.

Risks

Each tumor removal surgery carries certain risks that are inherent to the procedure. There is always a risk of misdiagnosing a cancer if an inadequate sample was procured during biopsy, or if the tumor was not properly located. There is a chance of infection of the surgical site, excessive bleeding, or injury to adjacent tissues. The possibility of metastasis and seeding are risks that have to be considered in consultation with an oncologist.

Results

The results of a tumor removal procedure depend on the type of tumor and the purpose of the treatment. Most benign tumors can be removed successfully with no risk of the abnormal cells spreading to other parts of the body and little risk of the tumor returning. Malignant tumors are considered successfully removed if the entire tumor can be removed, if a clear margin of healthy tissue is removed with the tumor, and if there is no evidence of metastasis. The normal results of palliative tumor removal are a reduction in the patient's symptoms with no impact on length of survival.

Morbidity and mortality rates

The recurrence rates of benign and malignant tumors after removal depend on the type of tumor and its location. The rate of complications associated with tumor removal surgery differs by procedure, but is generally very low.

Despite low rates of complication for the actual tumor removal procedures, cancer itself remains the second most frequent cause of death among Americans, responsible for about 25% of all deaths. In 2013, about 580,350 people in the United States were expected to die of cancer—about 1,600 deaths daily.

Alternatives

If a benign tumor shows no indication of harming nearby tissues and is not causing the patient any symptoms, surgery may not be required to remove it. Chemotherapy, radiation therapy, and biological therapy are treatments that may be used alone or in conjunction with surgery.

Health care team roles

Tumors are usually removed by a general surgeon or surgical oncologist. The procedure is frequently done in a hospital setting, but specialized outpatient facilities may sometimes be used.

Turner syndrome

Definition

Turner syndrome is a chromosomal disorder affecting females wherein one of the two X-chromosomes is defective or completely absent.

Demographics

The prevalence of Turner syndrome is widely reported as being approximately one per 2,000 live female births, with little difference among racial or ethnic groups. About 15% of spontaneous abortions of female fetuses have this genetic abnormality. The incidence of Turner syndrome seems to be slightly higher in fetuses conceived by older women.

A low hairline at the back of the neck is one of several characteristics of Turner syndrome. *(Custom Medical Stock Photo, Inc.)*

Description

Chromosomes are structures in the nucleus of every cell in the human body. Chromosomes contain the genetic information necessary to direct the growth and normal functioning of all cells and systems of the body. A normal individual has a total of 46 chromosomes in each cell, two of which are responsible for determining gender. Normally, females have two X-chromosomes (one from each parent) and males have one X and one Y-chromosome.

In Turner syndrome, an error occurring very early in development results in an abnormal number and arrangement of chromosomes. Most commonly, an individual with Turner syndrome will be born with 45 chromosomes in each cell rather than 46. The missing chromosome is an X-chromosome. The affected person is always female.

About 1–2% of all female conceptions have a missing X-chromosome. Of these, the majority (99%) spontaneously abort, usually during the first trimester of **pregnancy**. With **ultrasound** being used more frequently, researchers have realized that some pregnancies with a missing X-chromosome that

progress into the second trimester are associated with nuchal cysts, severe **lymphedema**, or hydrops fetalis. These pregnancies are associated with a high frequency of fetal death.

Causes and symptoms

Turner syndrome is a disorder associated with characteristic defects in the X-chromosome. The most common presentation is a female with a single X-chromosome and an absent X-chromosome. A Greek study from 1999 reported that the intact X-chromosome was as likely to come from the mother as from the father. This means that there is no parental pattern of responsibility for the missing or defective X-chromosome.

Another less common genetic pattern for Turner Syndrome (35%) is a mosaic. A Danish study reported that mosaicism has an effect on malformations that are associated with Turner syndrome. Researchers have found that XX/XO mosaic individual have a different growth pattern from children who are completely XO.

The exact location of the genes on the X-chromosome involved in Turner syndrome has not been determined as of 2014. Evidence exists that there is a locus for stature on the distal portion of the short arm of the X chromosome; there are loci for normal ovarian function on both the short and long arms; and there are loci contributing to fetal viability on the long arm of X.

Turner syndrome is characterized by retarded growth that leads to a small stature and frequent **infertility**. Individuals with Turner syndrome report an increased incidence of **fractures** in childhood and osteoporotic fractures in adulthood. The incidence of **diabetes mellitus** (both insulin dependent [type 1] and non-insulin dependent [type 2] varieties) has been reported increased in Turner syndrome. Ischemic **heart disease**, **stroke**, and **hypertension** are also more common.

Growth in children with Turner syndrome is characterized by a slight **intrauterine growth retardation**, relatively normal growth rates for the first several years of life, a progressive deceleration of growth later in childhood, and the lack of a pubertal growth spurt.

Most individuals with Turner syndrome are not mentally retarded. They may have some learning disabilities, particularly with regard to spatial perception, visual-motor coordination, and mathematics. As a result, the nonverbal IQ in Turner syndrome tends to be lower than the verbal IQ.

Cardiovascular malformations are well-recognized congenital anomalies in Turner syndrome. Dilation and dissection of the aorta are reported in approximately half of women with Turner syndrome. Heart valve abnormalities also are common. Because of the potential consequences of aortic dilation, some experts recommend screening all individuals with Turner syndrome.

Normal pubertal development and spontaneous menstrual periods do not occur in the majority of children with Turner syndrome. It is estimated that 3–8% of girls with a single X-chromosome and 12–21% of females with sex chromosome mosaicism may have normal pubertal development and spontaneous menstrual periods. A few pregnancies have been reported in women with Turner syndrome.

KEY TERMS

Aortic dissection—A tear in the aorta (the main blood vessel carrying blood away from the heart) that allows blood to flow between layers of the aorta, eventually causing it to fail.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Diabetes mellitus—A disease in which insufficient insulin is made by the body to metabolize sugars.

Hydrops fetalis—Extreme edema of the fetus.

Mosaic—A term referring to a genetic situation in which an individual's cells do not have the exact same composition of chromosomes. In mosaic Turner syndrome, some cells are normal and have two X chromosomes (XX), while others are abnormal and have only one X chromosome (XO).

Nuchal cysts—Small cysts in the fetus's neck that present in 1% of pregnancies.

Diagnosis

Turner syndrome is diagnosed on the basis of genetic analysis of chromosomes. This can be done prior to birth or after birth.

Treatment

Traditional

Because it is so dangerous, experts suggest screening for **aortic dissection**, although the specific timing

WWW.BOOKBAZ.IR

for this screening is controversial. **Plastic surgery** to correct webbing of the neck should be considered at an early age (before entering school) for girls with Turner syndrome.

Drugs

Most individuals with Turner syndrome require female hormone therapy to promote development of secondary sexual characteristics and menstruation. The time of beginning therapy varies with individuals. Experts recommend that therapy begin when a woman expresses concern about her onset of **puberty**.

All women receiving long-term, exogenous female hormone therapy require periodic gynecological examinations, because those with Turner syndrome have an increased risk of developing neoplasms such as gonadoblastoma and dysgerminoma, which arise from their rudimentary streak gonads.

Prognosis

Most women with Turner syndrome can live relatively normal lives. The prognosis for a person with Turner syndrome is dependent on other conditions that may be present. Care must be taken to regularly monitor the health problems that are associated with Turner syndrome. For example, heart or kidney defects, **hearing loss**, or the development of inflammatory bowel disease may significantly affect the quality of life. Without these types of conditions, their life expectancy is close to normal. Support will be necessary to help an adolescent girl cope with **body image** issues and to help some women accept the fact that they will never be able to have children.

Prevention

Turner syndrome is a genetic disorder that cannot be prevented. Prenatal testing may give parents information about whether their child has Turner syndrome and prepare them to make decisions about the child's future.

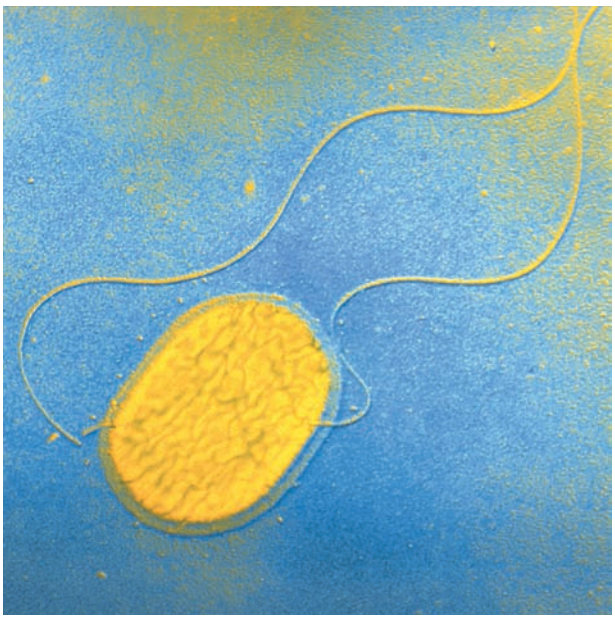
Typhoid fever

Definition

Typhoid **fever** is a severe infection caused by a bacterium, *Salmonella typhi*. *S. typhi* is in the same family of bacteria as the type spread by chicken and eggs, commonly known as salmonella **poisoning** or **food poisoning**. Unlike the bacteria that cause food poisoning, *S. typhi* bacteria do not have **vomiting** and **diarrhea** as the most prominent symptoms of their presence in humans. Instead, persistently high fever is the hallmark of *S. typhi* infection.



Transmission electron microscopy (TEM) scan of *Salmonella typhi*, the bacteria that causes typhoid fever in humans. *(Custom Medical Stock Photo, Inc.)*

Demographics

Typhoid fever is rare in industrialized countries with good sewage treatment and clean water supplies. In the United States in 2006, there were 314 reported cases. Of these, about 80% occurred in individuals who had traveled outside the United States to areas where typhoid fever is common. Those areas include Asia, Africa, Latin America, the Caribbean, and Oceania. Although typhoid fever can be found in all those areas, 80% of cases worldwide are found in Bangladesh, China, India, Indonesia, Laos, Nepal, Pakistan, and Vietnam. As of 2014, about 21.5 million people developed typhoid fever each year and 200,000 people died of the disease annually.

Description

Typhoid fever is passed from person to person through poor hygiene, such as incomplete or no hand washing after using the toilet. This allows *S. typhi* to enter the food and water supply. The bacteria are ingested and then passed into the stool and urine of infected patients. They may continue to be present in the stool of asymptomatic carriers—persons who have recovered from the symptoms of the disease but continue to carry the bacteria. This carrier state occurs in about 3% of all individuals who have recovered from typhoid fever. Persons who are carriers of the disease and who handle food can be the source of epidemic spread of typhoid. One such individual gave her name to the expression "Typhoid Mary," a name given to someone whom others avoid.

Causes and symptoms

S. typhi must be ingested to cause disease. Transmission often occurs when a person in the carrier state does not wash hands thoroughly (or not at all) after defecation and serves food to others. This pathway is sometimes called the fecal-oral route of disease transmission. In countries where open sewage is accessible to flies, the insects land on the sewage, pick up the bacteria, and then contaminate food to be eaten by humans. In countries with poor sewage treatment facilities, sewage can contaminate the water supply and typhoid fever can spread by drinking contaminated water.

After being swallowed, the *S. typhi* bacteria enter the digestive tract where they are taken in by cells called mononuclear phagocytes. These phagocytes are cells of the immune system, whose job it is to engulf and kill invading bacteria and viruses. In the case of *S. typhi*, however, the bacteria are able to survive ingestion by the phagocytes, and multiply within these cells. This period of time, during which the bacteria are multiplying within the phagocytes, is the 10- to 14-day incubation period of typhoid fever. When huge numbers of bacteria fill an individual phagocyte, they spill out of the cell and into the bloodstream, where their presence begins to cause symptoms.

The presence of increasingly large numbers of bacteria in the bloodstream (**bacteremia**) is responsible for an increasingly high fever, which lasts throughout the four to eight weeks of the disease in untreated individuals. Other symptoms of typhoid fever include **constipation** (at first), nausea, extreme **fatigue**, **headache**, joint **pain**, and a rash across the abdomen known as rose spots.

The bacteria move from the bloodstream into certain tissues of the body, including the gallbladder and lymph tissue of the intestine (called Peyer's patches). The tissue's response to this invasion causes symptoms ranging from inflammation of the gallbladder (**cholecystitis**) to intestinal bleeding to actual perforation of the intestine. Perforation of the intestine refers to an actual hole occurring in the wall of the intestine, with leakage of intestinal contents into the abdominal cavity. This leakage causes severe irritation and inflammation of the lining of the abdominal cavity, which is called **peritonitis**. Peritonitis is a frequent cause of death from typhoid fever.

MARY MALLON (1869–1938)

"Typhoid Mary". *(© Bettman/Corbis.)*

Mary Mallon was born in Cookstown, Ireland, on September 23, 1869, to Catherine Igo and John Mallon. As a teenager, Mallon left her parents and immigrated to New York to live with an aunt and uncle. Until 1906, when George A. Soper began to study an outbreak of typhoid fever in Long Island, little was known about Mallon.

Soper was called to identify possible causes of an eruption of typhoid fever at a summer house in Oyster Bay. After examining the food and water in a futile attempt to discover contaminants, Soper decided that the disease was probably transmitted by a human carrier. He soon learned that the cook had disappeared and tracked Mallon to her new place of employment, expecting her cooperation in dealing with the matter. Soper eventually turned the case over to the New York City Department of Health. When Mallon was ultimately caught, she refused treatment and was held for three years as a threat to the public. In 1910, a judge granted her release with the stipulation that she not seek employment as a cook, since the disease was transmitted through food. Mallon agreed but, in 1915, an outbreak of typhoid at a hospital was, once again, linked to her. When Soper investigated this incident he learned that employees had nicknamed one of the cooks "Typhoid Mary."

After Mallon was found, she was taken into custody, and spent the rest of her life at Riverside Hospital. Mallon died on November 11, 1938.

Other complications of typhoid fever include liver and spleen enlargement, sometimes so great that the spleen ruptures or bursts; anemia, or low red blood cell count due to blood loss from the intestinal bleeding; joint infections, which are especially common in patients with **sickle cell disease** and immune system disorders; **pneumonia** caused by a bacterial infection (usually *Streptococcus pneumoniae*), which is able to take hold due to the patient's weakened state; heart infections; and **meningitis** and infections of the brain, which cause mental confusion and even **coma**. It may take a patient several months to recover fully from untreated typhoid fever.

Diagnosis

In some cases, the doctor may suspect the diagnosis if the patient has already developed the characteristic rose spots, or if he or she has a history of recent travel in areas with poor sanitation. The diagnosis is confirmed by a **blood culture**. Samples of a patient's stool, urine, and bone marrow can also be used to grow *S. typhi* in a laboratory for identification under a microscope. Cultures are the most accurate method of diagnosis. Blood cultures usually become positive in the first week of illness in 80% of patients who have not taken **antibiotics**.

Treatment

Drugs

Antibiotics are the treatment of choice for typhoid fever. As of the mid 2010s, commonly used drugs are ceftriaxone and cefoperazone. Ciprofloxacin is sometimes given as follow-up therapy. It should be noted, that **antibiotic resistance** is common in *S. typhi*. Forty-three percent of samples of *S. typhi* collected from patients in the United States were resistant to at least one antibiotic. The choice of antibiotic(s) used to treat typhoid fever is determined by the origin of the disease, sensitivity of cultures of the bacterium to specific antibiotics, and response to treatment.

Carriers of *S. typhi* must be treated even when they do not show any symptoms of the infection, because carriers are responsible for the majority of new cases of typhoid fever. Eliminating the carrier state is a fairly difficult task. It requires treatment with one or even two different medications over a period of four to six weeks. The antibiotics most commonly given are ampicillin (sometimes given together with probenecid) and amoxicillin. In the case of a carrier with **gallstones**, surgery may need to be performed to remove the gallbladder. This measure is necessary because typhoid bacteria are often housed in the gallbladder, where they may survive in spite of antibiotic treatment. In some patients, treatment with rifampin and

KEY TERMS

Asymptomatic—A state in which a person experiences no symptoms of a disease.

Bacteremia—Bacteria in the blood.

Carrier—A person who has a particular disease agent present within his or her body, and can pass this agent on to others, but who displays no symptoms of infection.

Epidemic—A large number of cases of the same disease or infection all occurring within a short time period in a specific location.

Incubation period—The time between when an individual becomes infected with a disease-causing agent and when symptoms begin to appear.

Mononuclear phagocyte—A type of cell of the human immune system that ingests bacteria, viruses, and other foreign matter, thus removing potentially harmful substances from the bloodstream. These substances are usually then digested within the phagocyte.

Rose spots—A pinkish rash across the trunk or abdomen that is a classic sign of typhoid fever.

Sickle cell disease—An inherited disorder characterized by a genetic flaw in hemoglobin production. (Hemoglobin is the substance within red blood cells that enables them to transport oxygen.) The hemoglobin that is produced has a kink in its structure that forces the red blood cells to take on a sickle shape, inhibiting their circulation and causing pain. This disorder primarily affects people of African descent.

trimethoprim-sulfamethoxazole is sufficient to eradicate the bacteria from the gallbladder without surgery.

Prognosis

The prognosis for recovery is good for most patients. In the era before effective antibiotics were discovered, about 12% of all typhoid fever patients died of the infection. Now, fewer than 1% of patients who receive prompt antibiotic treatment will die. The mortality rate is highest in the very young and very old, and in patients with **malnutrition**. The most ominous signs are changes in a patient's state of consciousness, including stupor or coma.

Prevention

Hygienic sewage disposal systems in a community, good water treatment facilities, and proper personal hygiene are the most important factors in preventing typhoid fever. Immunizations are available for travelers who expect to visit countries where *S. typhi* is a known **public health** problem. Some of these immunizations provide only short-term protection (for a few months), while others may be effective for several years. Efforts are being made to develop vaccines that provide a longer period of protection with fewer side effects from the vaccine itself. The most commonly reported side effects are flu-like **muscle cramps** and abdominal pain.

Typhus

Definition

Several different illnesses are called "typhus," all of them caused by one of the bacteria in the family

WWW.BOOKBAZ.IR

Rickettsiae. Each illness occurs when the bacteria is passed to a human through contact with an infected insect.

Description

The four main types of typhus are:

- epidemic typhus
- Brill-Zinsser disease
- endemic or murine typhus
- scrub typhus

These diseases are all somewhat similar, although they vary in terms of severity. The specific type of *Rickettsia* that causes the disease also varies, as does the specific insect that can pass the bacteria along.

Epidemic typhus, which is sometimes called jail **fever** or louse-borne typhus, is caused by *Rickettsia prowazekii*, which is carried by body lice. When the lice feed on a human, they may simultaneously defecate. When the person scratches the bite, the feces (which carrys the bacteria) are scratched into the wound. Body lice are common in areas in which people live in overcrowded, dirty conditions, with few opportunities to wash themselves or their clothing. Because of this fact, this form of typhus occurs simultaneously in large numbers of individuals living within the same community; that is, in epidemics. This type of typhus occurs when cold weather, poverty, war, and other disasters result in close living conditions that encourage the maintenance of a population of lice living among humans. Some medical historians think that the Great **Plague** of Athens in 430 B.C. may have been epidemic typhus. Epidemic typhus is now found in the mountainous regions of Africa, South America, and Asia.

Brill-Zinsser disease is a reactivation of an earlier infection with epidemic typhus. It affects people years after they have completely recovered from epidemic typhus. When something causes a weakening of their immune system (like **aging**, surgery, illness), the bacteria can gain hold again, causing illness. This illness tends to be extremely mild.

Endemic typhus is carried by fleas. When a flea lands on a human, it may defecate as it feeds. When the person scratches the itchy spot where the flea was feeding, the bacteria-laden feces are scratched into the skin, thus causing infection. The causative bacteria is called *Rickettsia typhi*. Endemic typhus occurs most commonly in warm, coastal regions. In the United States, southern Texas and southern California have the largest number of cases.

Scrub typhus is caused by *Rickettsia tsutsugamushi*. This bacteria is carried by mites or chiggers. As the mites feed on humans, they deposit the bacteria. Scrub typhus occurs commonly in the southwest Pacific, southeast Asia, and Japan. It is a very common cause of illness in people living in or visiting these areas. It occurs more commonly during the wet season.

Causes and symptoms

The four types of typhus cause similar types of illnesses, though varying in severity.

Epidemic typhus causes fever, **headache**, weakness, and muscle aches. It also causes a rash composed of both spots and bumps. The rash starts on the back, chest, and abdomen, then spreads to the arms and legs. The worst types of complications involve swelling in the heart muscle or brain (encephalitis). Without treatment, this type of typhus can be fatal.

Brill-Zinsser disease is quite mild, resulting in about a week-long fever, and a light rash similar to that of the original illness.

Endemic typhus causes about 12 days of high fever, with chills and headache. A light rash may occur.

Scrub typhus causes a wide variety of effects. The main symptoms include fever, headache, muscle aches and pains, **cough**, abdominal **pain**, **nausea and vomiting**, and **diarrhea**. Some patients experience only these symptoms. Some patients develop a rash, which can be flat or bumpy. The individual spots eventually develop crusty black scabs. Other patients go on to develop a more serious disease, in which encephalitis, **pneumonia**, and swelling of the liver and spleen (hepatosplenomegaly) occur.

Diagnosis

A number of tests exist that can determine the reactions of a patient's antibodies (immune cells in the blood) to the presence of certain viral and bacterial markers. When the antibodies react in a particular way, it suggests the presence of a rickettsial infection. Many tests require a fair amount of time for processing, so practitioners will frequently begin treatment without completing tests, simply on the basis of a patient's symptoms.

Treatment

The **antibiotics** tetracycline or chloramphenicol are used for treatment of each of the forms of typhus.

KEY TERMS

Antibody—Specialized cells of the immune system, which can recognize organisms that invade the body (such as bacteria, viruses, and fungi). The antibodies are then able to set off a complex chain of events designed to kill these foreign invaders.

Bioterrorism—The use of disease microorganisms to intimidate or terrorize a civilian population.

Endemic—Occurring naturally and consistently in a particular area.

Epidemic—A large cluster of cases all occurring at about the same time within a specific community or region.

Prognosis

The prognosis depends on what types of complications an individual patient experiences. While children usually recover well from epidemic typhus, older adults may have as much as a 60% death rate without treatment. Brill-Zinsser, on the other hand, carries no threat of death. People usually recover uneventfully from endemic typhus, although the elderly, those with other medical problems, or people mistakenly treated with sulfa drugs may have a 1% death rate from the illness. Scrub typhus responds well to appropriate treatment, but untreated patients have a death rate of about 7%.

The relatively high death rate from untreated typhus is one reason why some researchers are concerned that its causative organisms might be used in the future as agents of bioterrorism.

Prevention

Prevention for each of these forms of typhus includes avoidance of the insects that carry the causative bacteria. Other preventive measures include good hygiene and the use of insect repellents.

Tzanck preparation

Definition

Tzanck preparation is a rapid test done to diagnose infections caused by herpesviruses. Cells are examined under a microscope for signs of infection.

Purpose

Herpesviruses are responsible for several superficial infections. Varicella zoster virus causes **chickenpox** and **shingles**, herpes simplex type 1 causes the **common cold** sore or **fever** blister, and herpes simplex type 2 causes the sexually transmitted disease **genital herpes**. They are all characterized by blisters and **ulcers**.

Physicians usually can diagnose herpes infections simply by looking at the type of blisters and ulcers, and their distribution on the person's body. Sometimes laboratory evidence of herpes is needed to confirm the diagnosis. For example, herpes can be devastating to a newborn baby or a person with a weakened immune system. Treatment can begin once herpes is confirmed in a laboring mother's genital ulcers or in the skin blisters of an immunocompromised person. A lab tries to grow (culture) the virus that may be present in the blister. This lab test takes several days to complete, but the Tzanck preparation takes minutes.

Description

The Tzanck preparation is done by smearing cells taken from a fresh blister or ulcer onto a microscope slide. The cells are stained with a special stain, such as Wright's stain, and then examined under a microscope for characteristic changes caused by a herpesvirus. Herpes causes giant cells with multiple nuclei. The shape of each nucleus appears molded to fit together with those adjacent. The background of the cell looks

like ground glass and contains small dark spots called inclusion bodies.

Tzanck preparation is also called a Tzanck smear, herpes stain for inclusion bodies, or inclusion bodies stain. Results are available the same or following day, often within minutes.

Preparation

A fresh blister is opened with a scalpel or sterile needle. The physician scrapes the base of the blister with the scalpel, gathers as much cellular material as possible, and gently spreads it on a microscope slide.

Results

A normal smear shows no evidence of a herpes infection. This test may also have false negatives. Studies have shown that the Tzanck preparation shows signs of infection in only 50–79% of people with a herpes infection. A negative Tzanck preparation may have to be confirmed by a herpes culture.

Abnormal results

A smear that shows evidence of herpes infection does not distinguish between the various infections caused by herpes virus. The physician uses the person's symptoms and other clinical findings to distinguish between these infections. In certain cases, the physician will follow a positive Tzanck smear with a culture for confirmation.

Ulcer surgery

Definition

Ulcer surgery is a procedure used to cure peptic ulcer disease when medications have failed.

Purpose

Ulcer surgery is used to relieve a present peptic ulcer disease and to prevent recurrence of it.

Surgery is usually required if the ulcer is in one of the following states:

- perforated and overflowed into the abdomen
- scarred or swelled so much that the bowel is obstructed
- acute bleeding
- defied all other types of treatment

The need for ulcer surgery has diminished greatly over the past 20–30 years due to the discovery of two new classes of drugs and the presence of the causal germ *Helicobacter pylori* in the stomach. The drugs are the H2 blockers, such as cimetidine and ranitidine, and the **proton pump inhibitors**, such as omeprazole. These effectively arrest acid production. *H. pylori* can be eliminated from most patients with a combination of **antibiotics** and bismuth.

Precautions

There is a tumor of the pancreas that produces a hormone called gastrin. Gastrin causes ulcers by stimulating acid production. If this disease—Zollinger-Ellison syndrome—does not respond to medical treatment, either the tumor or the entire stomach must be removed.

Description

The two primary goals of ulcer surgery, elimination of the current problem and prevention of future problems bring with them a third problem—to perpetuate the normal function of the bowel. The vagus nerves relax the pylorus, allowing the stomach to empty. Cutting the vagus nerves, while reducing the stomach's acid production, also prevents stomach emptying. Therefore, the procedures described must guarantee stomach emptying along with their other goals.

Total gastrectomy

Removing the entire stomach is done only for resistant Zollinger-Ellison syndrome or extensive cancers.

Antrectomy

The lower half of the stomach makes most of the acid and gets all the peptic ulcers above the duodenum. Removing it leaves little place for ulcers to form and little acid to produce them.

Vagotomy

Cutting the vagus nerves can be done in three ways:

- the main nerves can be cut completely as they enter the abdomen from the chest
- the branches that go to the stomach can be cut as they leave the main nerves
- the tiny branches that stimulate acid production can be cut on the surface of the stomach

Pyloroplasty

Opening up the valve at the outlet of the stomach guarantees that the stomach can empty, even without vagus nerve stimulation. **Pyloroplasty** is ordinarily done by cutting across the muscle that surrounds the outlet. It can also be done by passing a balloon down from the mouth and inflating it forcefully to stretch out the pylorus (opening from the stomach to the intestine).

Close perforation

For some patients all that can be done is to close the hole in the bowel and wait for the patient to recover before initiating corrective surgery.

Billroth I and II

After removing a piece of the stomach, the remainder must be reattached to the rest of the bowel. Simply joining the upper stomach back to the duodenum is called a Billroth I or gastroduodenostomy. It is sometimes better to attach the stomach with another piece of bowel (the jejunum), creating a "y" with the bile drainage and the duodenum forming the second branch of the "y." This part of the procedure is called a gastrojejunostomy. A gastroenterostomy is a more general term for connecting the stomach with any piece of bowel.

A selective **vagotomy** can be done alone. A complete vagotomy requires either a pyloroplasty or antrectomy. An antrectomy must be reconnected with either a Billroth I or a Billroth II.

Some of these procedures are now being done through a laparoscope.

Risks

All of these procedures carry risks, generally in proportion to their benefits. The more extensive surgeries, such as vagotomy and antrectomy with Billroth II reconnection, have the highest success rate and the highest complication rate.

common usage, however, ulcer usually is used to refer to disorders in the upper digestive tract.

Demographics

It is estimated that 2% of the adult population in the United States has active peptic **ulcers**, and that about 10% will develop ulcers at some point in their lives. There are about 500,000 new cases of peptic ulcer in the United States every year, with as many as 4 million recurrences. The male/female ratio for ulcers of the digestive tract is 3:1.

The most common forms of peptic ulcer are duodenal and gastric. About 80% of all ulcers in the digestive tract are duodenal ulcers. This type of ulcer may strike people in any age group but is most common in males between the ages of 20 and 45. The incidence of duodenal ulcers has dropped over the past 30 years. Gastric ulcers account for about 16% of peptic ulcers. They are most common in males between the ages of 55 and 70. The single most common cause of gastric ulcers is the use of **nonsteroidal anti-inflammatory drugs**, or NSAIDs. The widespread use of NSAIDs is thought to explain why the incidence of gastric ulcers in the United States is rising.

Description

The terms ulcer, gastric ulcer, and peptic ulcer often are used loosely and interchangeably. Peptic ulcers can develop in the lower part of the esophagus, the stomach, the first part of the small intestine (the duodenum), and the second part of the small intestine (the jejunum).

Causes and symptoms

There are three major causes of peptic ulcers: infection, certain types of medication, and disorders that cause oversecretion of stomach juices.

Helicobacter pylori infection

Helicobacter pylori is a rod-shaped gram-negative bacterium that lives in the mucous tissues that line the digestive tract. Infection with *H. pylori* is the most common cause of duodenal ulcers. About 95% of patients with duodenal ulcers are infected with *H. pylori*, as opposed to only 70% of patients with gastric ulcers.

Nonsteroidal anti-inflammatory drugs (NSAIDS)

Nonsteroidal anti-inflammatory drugs, or NSAIDs, are painkillers that many people use for headaches, sore muscles, arthritis, menstrual cramps, and similar complaints. Many NSAIDs are available without prescriptions. Common NSAIDs include **aspirin**, ibuprofen (Advil, Motrin), flurbiprofen (Ansaid, Ocufen), ketoprofen (Orudis), and indomethacin (Indacin). Chronic NSAID users have 40 times the risk of developing a gastric ulcer as nonusers. Users also are three times more likely than nonusers to develop bleeding or fatal complications of ulcers. Aspirin is the NSAID that is most likely to cause ulcers.

Other syndromes and disorders

Fewer than 5% of peptic ulcers are due to Zollinger-Ellison syndrome, a disorder in which small tumors, called gastrinomas, secrete a hormone (gastrin) that stimulates the production of digestive juices. Because of this excess secretion, these disorders are sometimes called hypersecretory syndromes.

Risk factors

Smoking is an important risk factor that increases a patient's chance of developing an ulcer, decreases the body's response to therapy, and increases the chances of dying from ulcer complications. Blood type appears to be a predisposing factor for ulcer location; people with type A blood are more likely to have gastric ulcers, while those with type O are more likely to develop duodenal ulcers. The role of emotional **stress** in ulcer development is currently debated. Present research indicates that an individual's attitudes toward stress, rather than the amount of stress by itself, is a better predictor of vulnerability to peptic ulcers. Preferences for high-fat or spicy foods do not appear to be significant risk factors.

DISCOVERY OF *HELICOBACTER PYLORI*

Australian scientist Barry Marshall at the Queen Elizabeth II hospital in Perth Marshall and fellow Australian Robin Warren won the 2005 Nobel Prize. *((c) Tony McDonough/epa/Corbis.)*

J. Robin Warren (b. 1937) and Barry Marshall (b. 1951), two Australians, changed the medical community's understanding of stomach ulcers and stomach cancer forever when they discovered the bacterium *Helicobacter pylori* and identified its role in causing stomach disease.

Until Warren and Marshall's pioneering work, the causes of stomach ulcers were thought to be well understood. The medical community believed that the stomach produced too much acid, usually due to stress and other lifestyle factors, leading to inflammation and eventually to ulcers. The accepted course of treatment was to prescribe antacid medications. In severe cases, surgery was performed to remove a portion of the lower stomach. Thousands of individuals died annually of stomach cancer and complications related to stomach ulcers or the surgeries performed to treat them.

Warren was working as a hospital pathologist when he noticed that an s-shaped bacterium, *H. pylori*, was present in many biopsies he examined from patients' stomachs. Of special interest was that fact the bacterium seemed to be associated with an inflammation of the stomach membrane and that inflammation was often associated with stomach ulcers and stomach cancer. Marshall, who was at this time a clinical fellow in the same hospital, became interested in Warren's findings and decided to pursue a research project on the subject. In April 1982, the doctors took samples from the stomachs of 100 patients and sent these samples to the lab to be cultured.

At first the findings were inconclusive, but after more than 30 samples had been cultured, the researchers discovered that *H. pylori* required more than a few days to grow. Most bacteria grow much more quickly, and the laboratory had been giving up and discarding the samples before *H. pylori* was detectable. Giving the samples enough time to grow allowed the laboratory to identify the bacterium in all the patients in their sample who had ulcers. Additional work showed that the bacterium could easily be killed with antibiotics.

At the time, the medical community was firmly entrenched in its belief about the causes of ulcers. At first physicians were unwilling to accept these new findings. Marshall and Warren were unable to obtain funding for a clinical trial or permission to do experiments with human subjects. Frustrated by watching patients suffer who could be cured, Marshall drank a mixture containing *H. pylori* to do a definitive experiment on himself. He became quite ill and then cured himself with antibiotics, demonstrating that the bacterium could cause serious gastric distress and could be treated successfully.

Marshall and Warren did most of their work in the early 1980s, but not until the mid-1990s did the medical community begin to accept their findings. At that time, the tide shifted quickly, and treatment with antibiotics became standard for treating stomach ulcers. In 2005, the doctors were awarded the Nobel Prize in Physiology or Medicine for their groundbreaking work.

Gastric ulcers

The symptoms of gastric ulcers include feelings of **indigestion** and **heartburn**, weight loss, and repeated episodes of gastrointestinal bleeding. Ulcer **pain** often is described as gnawing, dull, aching, or resembling hunger pangs. The patient may be nauseated and have loss of appetite. About 30% of patients with gastric ulcers are awakened by pain at night. Many patients have periods of chronic ulcer pain alternating with symptom-free periods that last for several weeks or months. This characteristic is called periodicity.

Duodenal ulcers

The symptoms of duodenal ulcers include heartburn, stomach pain relieved by eating or **antacids**, weight gain, and a burning sensation at the back of the throat. The patient is most likely to feel discomfort two to four hours after meals, or after having citrus juice, coffee, or

KEY TERMS

Helicobacter pylori—A gram-negative rod-shaped bacterium that lives in the tissues of the stomach and causes inflammation of the stomach lining.

aspirin. About 50% of patients with duodenal ulcers awake during the night with pain, usually between midnight and 3 a.m. A regular pattern of ulcer pain associated with certain periods of day or night or a time interval after meals is called rhythmicity.

Not all digestive ulcers produce symptoms; as many as 20% of ulcer patients have so-called painless or silent ulcers. Silent ulcers occur most frequently in the elderly and in chronic NSAID users.

Diagnosis

Examination

The diagnosis of peptic ulcers should rarely be made on the basis of a **physical examination** alone. Many ulcer diagnoses based solely on physical exams actually are only **dyspepsia**, or upper adnominal pain and discomfort not caused by ulcers. The only significant finding may be mild soreness in the area over the stomach when the doctor presses (palpates) it. The doctor is more likely to suspect an ulcer if the patient has one or more of the following risk factors:

- male sex
- age over 45
- recent weight loss, bleeding, recurrent vomiting, jaundice, back pain, or anemia
- history of using aspirin or other NSAIDs
- history of heavy smoking
- family history of ulcers or stomach cancer

Tests

Blood tests usually give normal results in ulcer patients without complications. They are useful, however, in evaluating anemia from a bleeding ulcer or a high white cell count from perforation or penetration. Serum gastrin levels can be used to screen for Zollinger-Ellison syndrome.

It is important to test for *H. pylori* because almost all ulcer patients who are not taking NSAIDs are infected. Noninvasive tests include blood tests for immune response and a breath test. In the breath test, the patient is given an oral dose of radiolabeled urea. If *H. pylori* is present, it will react with the urea and the patient will exhale radiolabeled carbon dioxide. Invasive tests for *H. pylori* include tissue biopsies and cultures performed from fluid obtained by **endoscopy**.

Procedures

An endoscopy is considered the best procedure for diagnosing digestive ulcers and for taking samples of stomach tissue for biopsies. An endoscope is a slender tube-shaped instrument that allows the doctor to view the tissues lining the stomach and duodenum. Duodenal ulcers are rarely malignant. If the ulcer is in the stomach, however, the doctor will take a tissue sample because 3–5% of gastric ulcers are malignant.

Radiological studies are sometimes used instead of endoscopy because they are less expensive, more comfortable for the patient, and are 85% accurate in detecting malignancies.

Treatment

Drugs

Most drugs that are currently given to treat ulcers work either by lowering the rate of stomach acid secretion or by protecting the mucous tissues that line the digestive tract.

Medications that lower the rate of stomach acid secretions fall into two major categories: **proton pump inhibitors**, which bind an enzyme that secretes stomach acid, and H_2 receptor antagonists, which work by reducing intracellular acid secretion. The proton pump inhibitors include omeprazole (Prilosec) and lansoprazole (Prevacid). The H_2 receptor antagonists include ranitidine (Zantac), cimetidine (Tagamet), famotidine (Pepcid), and nizatidine (Axid).

The drugs used to protect the stomach tissues are sucralfate (Carafate), which forms a paste-like substance that clings to the mucous tissues and prevents further damage from stomach acid, and bismuth preparations. A third type of protective drug includes misoprostol (Cytotec), which is often given to patients with ulcers caused by NSAIDs.

Surgery

Surgical treatment of ulcers is generally used only for complications and suspected malignancies. The

most common surgical procedures used are vagotomies, in which the connections of the vagus nerve to the stomach are cut in order to reduce acid secretion, and antrectomies, which involve the removal of a part of the stomach (the antrum).

Eradication of Helicobacter pylori

Most doctors presently recommend treatment to eliminate *H. pylori* in order to prevent ulcer recurrences. Without such treatment, ulcers recur at the rate of 80% per year. A 2003 report showed that eradication *H. pylori* alone usually prevents recurring bleeding ulcers. The usual regimen used to eliminate the bacterium is a combination of tetracycline, bismuth subsalicylate (Pepto-Bismol), and metronidazole (Metizol, Flagyl).

Alternatives

Alternative treatments can relieve symptoms and promote healing of ulcers. A primary goal of these treatments is to rebalance the stomach's hydrochloric acid output and to enhance the mucosal lining of the stomach.

Botanical medicine offers a variety of remedies that may be helpful in ulcer treatment. Deglycyrrhizinated licorice or DGL, in a chewable or powder form, can help heal the mucous membranes and increase mucous so that it mixes with saliva to protect the membranes. Raw cabbage juice, high in glutanic acid, is very effective in healing an ulcer (one quart per day in divided doses). Soothing herbs, such as plantain (*Plantago major*), marsh mallow (*Althaea officinalis*), and slippery elm (*Ulmus fulva*); astringent herbs, such as geranium (*Pelargonium odoratissimum*); and the antimicrobial herb goldenseal (*Hydrastis canadensis*) can all be effective. Nutritionists advise taking antioxidant nutrients, including **vitamins** A, C, and E, zinc, and selenium.

Home remedies

Food allergies have been pointed to as a major cause of peptic (stomach) ulcers. An elimination/challenge diet can help identify the allergenic food(s) and continued elimination of these foods can assist in healing the ulcer. People with ulcers should not take aspirin. They also should stop smoking, since smoking irritates the mucosal lining of the stomach. Antacids should be avoided by anyone with an ulcer, because they can cause a rebound effect of increasing gastric acid secretion, as well as deplete vital nutrients necessary for healing. **Stress reduction** is also important for people with ulcers.

Prognosis

The prognosis for recovery from ulcers is good for most patients. Very few ulcers fail to respond to the medications that are currently used to treat them. Recurrences can be eliminated completely or cut to 5% by eradication of *H. pylori*. Most patients who develop complications recover without problems even when emergency surgery is necessary.

Complications

Between 10% and 20% of peptic ulcer patients develop complications at some time during the course of their illness. All of these are potentially serious conditions. Complications are not always preceded by diagnosis of or treatment for ulcers; as many as 60% of patients with complications have not had prior symptoms.

Bleeding is the most common complication of ulcers. It may result in anemia, **vomiting** blood (hematemesis), or the passage of bright red blood through the rectum (melena). About half of all cases of bleeding from the upper digestive tract are caused by ulcers. The mortality rate from ulcer hemorrhage is 6–10%.

About 5% of ulcer patients develop perforations, which are holes in the duodenal or gastric wall through which the stomach contents can leak out into the abdominal cavity. The incidence of perforation is rising because of the increased use of NSAIDs, particularly among the elderly. The signs of an ulcer perforation are severe pain, **fever**, and tenderness when the doctor touches the abdomen. Most cases of perforation require emergency surgery. The mortality rate is about 5%.

Ulcer penetration is a complication in which the ulcer erodes through the intestinal wall without digestive fluid leaking into the abdomen. Instead, the ulcer

penetrates into an adjoining organ, such as the pancreas or liver. The signs of penetration are more severe pain without rhythmicity or periodicity and the spread of the pain to the lower back.

Obstruction of the stomach outlet occurs in about 2% of ulcer patients. It is caused by swelling or scar tissue formation that narrows the opening between the stomach and the duodenum (the pylorus). Over 90% of patients with obstruction have recurrent vomiting of partly digested or undigested food; 20% are seriously dehydrated. These patients usually feel full after eating only a little food and may lose weight.

Prevention

Strategies for the prevention of ulcers or their recurrence include the following:

- eradication of *H. pylori* in patients already diagnosed with ulcers
- giving misoprostol to patients who must take NSAIDs
- avoiding unnecessary use of aspirin and NSAIDs
- giving up smoking
- cutting down on alcohol, tea, coffee, and sodas containing caffeine

Ultrasound

Definition

Medical ultrasound imaging involves the use of high frequency sound waves to produce images of different parts of the inside of the body. This medical procedure is painless, safe, and noninvasive. Ultrasound imaging uses sound waves to visualize internal body structures, as opposed to techniques like x ray, which uses radiation. Ultrasound images provide dynamic images in "real time" and not just a static picture taken at a single moment such as in x ray. Therefore, ultrasound imaging can help to show movement inside of body organs as well as the structure of the organs. Most people are familiar with ultrasound imaging being used during **pregnancy** to look safely and carefully at the developing fetus. There are also many other uses in medicine for ultrasound imaging.

The following are some other uses for medical ultrasound imaging:

- Cardiac ultrasound is used to diagnose problems with the heart and major blood vessels surrounding the heart.
- Ultrasound imaging in gynecology is used to diagnose problems with the female reproductive tract including being used to diagnose problems associated with infertility. Ultrasound is also used to monitor infertility treatments.
- Ultrasound imaging is used to look for problems with other internal organs, such as the gallbladder, bladder, testicles, liver, spleen, kidneys, and pancreas.

WWW.BOOKBAZ.IR

- Ultrasound imaging is also used to look for problems with glands, such as the thyroid.
- Vascular ultrasound imaging is used to watch the blood flow in blood vessels or blood flow to tumors. Ultrasound doppler imaging and color flow mapping can show the flow of blood.
- Ultrasound imaging is also used during medical procedures such as needle biopsies or egg retrieval during in vitro fertilization.

Purpose

The purpose of ultrasound imaging in medicine is to help the physician diagnose, monitor and treat medical conditions.

Description

Ultrasound imaging is performed by using a transducer, which is a small device that technicians hold in their hand and is attached to a cord that connects to the ultrasound machine. The ultrasound machine has a keyboard, a computer, and a display screen. The patient is usually lying down on an examination table and clear gel (cold or warm) is applied to the area of the body that is to be imaged or scanned so that the transducer makes easy contact with the body and can easily be slid back and forth during the ultrasound. As the transducer is moved over that part of the body, it sends out high frequency sound waves, looks for the returning echo and instantly puts that image up onto the screen. An ultrasound examination is usually painless; however, on occasion, discomfort from the pressure being pressed on the body may occur, especially if the patient's bladder is full, or if the area being scanned is injured or tender. Sometimes ultrasound imaging is performed by using an ultrasound probe that is inserted into an area of the body, such as the vagina or the esophagus. Vaginal ultrasounds are used to scan for early pregnancy or to look carefully at the ovaries or guide the physician during procedures such as egg retrieval for **in vitro fertilization**. This ultrasound is not usually painful, but to some may be uncomfortable. **Transesophageal echocardiography** involves inserting a narrow, flexible tube with a transducer in its tip into the throat. This allows the viewing of high-quality images of the heart, its valves and blood vessels, and the presence of any clots. Ultrasound may also be used to guide the placement of a needle when aspirating a tumor for a biopsy.

Precautions

The greatest precaution that should be taken when using ultrasound imaging to diagnose medical problems is the over and under diagnosing of problems by staff that is not properly trained, using poor equipment or not adequately supervised. This is especially true in the obstetrical setting where it is important to have properly trained ultrasound technicians (sonographers) to perform routine and advanced diagnostic ultrasounds on pregnant women. The Society of Diagnostic Medical Sonography and the American Institute for Ultrasound in Medicine are great resources for helping to find certified sonographers from accredited programs.

Preparation

Preparation for an ultrasound examination depends upon the area of the body that is to be scanned. For example, during pregnancy, a patient may be instructed to drink water and not to empty her bladder prior to the ultrasound examination to help with visualization during the ultrasound. Other procedures may require no eating or drinking prior to the ultrasound examination. Comfortable, loose clothing should be worn, although a gown may be provided to be worn for the ultrasound examination. It is important to ask for and follow the instructions that are given prior to the ultrasound examination so that the procedure does not need to be rescheduled.

Aftercare

After the ultrasound, the gel is wiped off and the patient is usually able to return to normal activity. Usually, after the examination, the technician has the images reviewed by the physician and the physician may then speak to the patient at that time. Otherwise, the results are called to the patient or discussed at a later visit. On occasion, especially during pregnancy, the technician or physician will discuss the results of the ultrasound while the ultrasound is being performed. If an ultrasound examination shows abnormal results, those results may need to be followed-up with other tests or consultations to discuss possible treatment.

Risks

For routine diagnostic ultrasound imaging, there are no known risks to humans and therefore, if necessary it is safe to repeat the procedure as often as needed to monitor a particular health concern or treatment. For over 30 years, diagnostic ultrasound imaging has been used on pregnant women. A multitude of studies on the effects of ultrasound use during pregnancy have been reported and although there have been a number of small studies citing possible hearing problems, low birth-weight and left handedness, these studies have not been verified by larger studies. Overall, there has been no evidence that ultrasound is

harmful to a developing fetus; however, the medical community should be diligent about preventing unnecessary use of ultrasound in pregnancy.

Ultraviolet light treatment

Definition

Ultraviolet light treatment uses a particular band of the nonvisible light spectrum to treat **psoriasis** and a variety of other skin diseases. It can be used alone or in combination with other medications applied directly to the skin or taken internally.

Purpose

Ultraviolet (UV) light treatment is used primarily in cases of severe psoriasis that have not responded to other medications or in cases affecting large portions of the body. Patients will typically receive a series of 3–5 weekly treatments for a month or more to bring their psoriasis symptoms into check. They may also receive periodic maintenance treatments to prevent recurrence of their psoriasis. Other skin conditions treated with UV light treatments are **vitiligo**, a condition in which people lose pigmentation in large patches of their skin, and **atopic dermatitis**, an allergy-related skin condition that produces itchy, reddish, and scaly patches of skin.

Precautions

Exposure to UV radiation is known to prematurely age the skin over time and increase the risk of **skin cancer**. These potential effects should be weighed against the potential benefits of the treatment. A history will be taken regarding sun exposure and burning; medications, such as **diuretics**, that may increase UV sensitivity exposure; and any history of skin cancers. Sometimes, UV light treatments are given in combination with photosensitizing agents, which maximize UV's effects on the skin. Patients who receive these agents, called psoralens, must take care to avoid exposure to sunlight, which also contains UV radiation. Exposure to UV radiation can also cause **cataracts** and other eye damage, so the patient's eyes must be adequately shielded during the treatments.

Description

UV light treatment can employ one of two bands of the ultraviolet spectrum: ultraviolet A (UVA), and ultraviolet B (UVB). Patients receive full-body treatments in special light boxes; smaller areas of the skin are sometimes treated with hand-held devices.

Treatment

UVB treatment

Psoriasis is the most common skin disease treated with UVB light treatment. Its mechanism of action remains unclear, but investigators speculate it may kill abnormal skin cells or alter immune system reactions in the skin. Most patients require 18–30 treatments before substantial improvement or complete clearing is seen. The intensity of the UV applied will vary depending on the patient's skin type. Fair-skinned patients will start with a relatively weaker dose; dark-skinned patients, a stronger dose. Physicians will first expose a small area of skin to UVB to determine the minimum erythema dose (MED), the minimum amount of UVB that produces redness 24 hours after exposure. Patients will be exposed for short times early in the treatment cycle, but these times will gradually increase over time.

The Goeckerman regimen, a treatment that combines UVB light with coal tar applied to the skin, is among the oldest and most frequently used treatments for patients with moderate to severe psoriasis. The coal tar is a photosensitizing agent and when it interacts with UVB, it appears to limit the abnormal turnover of skin cells characteristic of psoriasis. Although treatments with UVB and coal tar are highly effective, many

WWW.BOOKBAZ.IR

patients dislike the smell. Some investigators believe that the use of petroleum jelly or other emollients is just as effective as the coal tar preparations.

In addition to their UVB treatments, many patients will receive such systemic agents as methotrexate, a drug used in severe case of psoriasis, and certain **vitamin A** derivatives called retinoids. A newer retinoid called bexarotene (Targretin), which was originally developed to treat **cutaneous T-cell lymphoma**, shows promise as a treatment for psoriasis in combination with UVB therapy.

Another new development in UV therapy is the use of a laser as the source of the UVB radiation. The type of laser that is used is known as a 308-nm excimer laser, which uses a specific mixture of gases to produce high-intensity, short pulses of UV light.

PUVA treatment

Psoralens are photosensitizing agents found in plants. They have been known since ancient Egypt but have only been available in a chemically synthesized form since the 1970s. Psoralens are taken systemically or can be applied directly to the skin. The psoralens allow a relatively lower dose of UVA to be used. When they are combined with exposure to UVA in PUVA, they are highly effective at clearing psoriasis. Like UVB light treatments, the reason remains unclear, though investigators speculate there may be similar effects on cell turnover and the skin's immune response.

Choosing the proper dose for PUVA is similar to the procedure followed with UVB. The physician can choose a dose based on the patient's skin type. Often, however, a small area of the patient's skin will be exposed to UVA after ingestion of a psoralen. The dose of UVA that produces uniform redness 72 hours later, called the minimum phototoxic dose (MPD), becomes the starting dose for treatment.

Some patients experience nausea and **itching** after ingesting the psoralen compound. For these patients "bath PUVA" may be a good option.

Preparation

No major preparation is required for UV light treatments. Areas of the skin that are especially sensitive to the effects of UV light, such as the groin, backside, or face, are shielded during the treatments. Areas not affected by psoriasis are also covered. Special goggles are worn to protect the eyes. Some physicians apply an emollient, such as petroleum jelly, to the skin or other topical agents, such as coal tar, to enhance the results. In PUVA treatments, the psoralen is usually taken one hour before the treatment.

KEY TERMS

Erythema—The medical term for redness of the skin produced by congestion of the capillaries in the skin.

Goeckerman regimen—UVB light therapy combined with topical coal-tar preparations.

Minimum erythema dose—The minimum amount of UVB that produces redness 24 hours after exposure. It is the starting dose for UVB light treatments.

Minimum phototoxic dose—The dose of UVA that produces uniform redness 72 hours after ingesting a psoralen compound. It becomes the starting dose for PUVA treatment.

Psoralen—A family of photosensitizing chemicals that can be found in lemons, celery, and other plants. Chemically synthesized versions are used to augment the effects of UVA light treatments.

PUVA treatments—Treatments with the photosensitizers called psoralens and UVA.

Ultraviolet light—A portion of the light spectrum not visible to the eye. Two bands of the UV spectrum, UVA and UVB, are used to treat psoriasis and other skin diseases.

Aftercare

No major aftercare is required following UV light treatments. Patients, however, must take great care to limit or eliminate other exposures to UV radiation, such as from sunlight or **tanning** beds, because of the increased risk of premature **aging** of the skin and the development of skin cancers. Patients should monitor their skin closely for any signs of precancerous or cancerous skin growths in the future.

Risks

People who receive UV light treatments are at higher risk of premature aging of the skin and of developing skin cancer. These risks should be balanced against the benefits of treatment. Patients must also take care to limit or eliminate their exposure to other sources of UV radiation, especially if they are taking a psoralen compound in addition to receiving the UV treatments.

Results

Psoriasis will normally show significant improvement to complete healing with three to five UVB treatments a week for about four to five weeks. PUVA

treatments may require a bit longer to take effect, but because the overall dosage of UV is lower, they are thought by some investigators to be a safer alternative to UVB treatments.

Abnormal results

Modern light boxes carefully control the dosage of UV radiation and the exposure time. Overdose or overexposure is possible, however, and can lead to severe **burns**. It is important to choose a treatment provider who is experienced in the technique. It is also important to tell the physician about all medications being taken by the patient. Some medications, either alone or in combination with a psoralen, can provoke an extreme reaction to UV radiation. One medication that has been shown to be helpful in treating burns caused by overexposure to UV radiation is a gel containing a platelet-activating antagonist factor, or PAF, known as WEB 2086.

Umbilical cord blood banking

Definition

Umbilical cord blood banking is the practice of preserving for future use fetal blood that remains in the umbilical cord at the time of birth.

Purpose

During **pregnancy**, a developing fetus is attached to its mother's placenta by the umbilical cord. At birth, this cord is cut, and the placenta is expelled from the mother. Some fetal blood remains in the umbilical cord. Normally, this blood, along with the cord and the placenta, are simply disposed of. However, now there are ways to freeze the cord blood for future use.

Umbilical cord blood is special because it contains a lot of cells called hematopoietic stem cells. A stem cell is an unspecialized master cell that can develop into several different kinds of specialized cells. Hematopoietic stem cells normally develop into red blood cells that carry oxygen, white blood cells that fight infection, and platelets that help make blood clot. These hematopoietic stem cells are *not* the same as embryonic stem cells that are at the center political and ethical debate about their use in research. Their collection does not harm either the mother or the baby.

There are two other sources of hematopoietic stem cells—bone marrow and peripheral blood. Bone marrow is the spongy material inside bones that is the source for new blood cells produced throughout an individual's life. Peripheral blood is the blood that circulates through the body.

All cells have a protein profile that identifies them. When a foreign cell enters the body, immune system cells recognize the protein profile as foreign and attack the cell. The advantage of umbilical cord stem cells that they are more immature and have a less well developed protein profile than bone marrow or peripheral stem cells. As a result, they draw a weaker response from the body's immune system.

The protein profile of human cells is called the human leukocyte antigen (HLA) profile. Normally for transplanted cells such as bone marrow cells to be accepted, there must be a close to perfect match between the HLA profile of the donor and the recipient. Since there are over 10,000 HLA types, finding an exact match can be difficult. Because umbilical cord blood cells have a less well developed HLA profile, they do not have to match the recipient's HLA as closely to be accepted by the immune system of the transplant recipient.

Types of cord blood banks

There are two types of umbilical cord blood banks—private and public. Private blood cord banks can be for-profit or not-for-profit. They sell kits that can be used at any delivery to collect cord blood. They also charge a yearly fee to store the blood. The cord blood is available only to the child or members of the child's family from which it came. It is a perfect HLA match to child's blood. When a transplant is done using cells that came from the individual who needs the transplant, it is called an autologous transplant. Autologous transplants have a high rate of success.

Public cord banks do not charge a fee to collect or store cord blood. Parents of newborns donate the cord blood, and it is then available to anyone who needs it and is an appropriate match. This type of transplant where the recipient is not the same as the donor is called an allogeneic transplant. Much of the success of allogeneic transplants depends on finding a good HLA match. Because of funding considerations, there are a limited number of public cord blood banks. To donate to a public blood cord bank, the mother must give birth in a facility associated with a public blood cord bank.

How cord blood is used

The first successful umbilical cord **stem cell transplantation** occurred in 1988, when a newborn girl donated cord blood to cure her brother of Fanconi's anemia, a genetic defect. Many other blood diseases can now be treated successfully with cord stem cell transplants. These same diseases can be treated with bone marrow transplant if an appropriately matched donor can be found. In addition, research is ongoing in the hope that cord blood stem cells can be induced to differentiating into other types of cells, such as nerve cells, that can be used to treat other diseases.

Some diseases treated with blood stem cell transplant include:

- acute lymphatic leukemia
- acute myelogenous leukemia
- chronic myelogenous leukemia
- Hodgkin disease
- non-Hodgkin lymphoma
- neuroblastoma
- severe combined immune deficiency
- anapalstic anemia
- thalassemia
- sickle cell anemia
- Fanconi's anemia

In addition to being more readily accepted by the donor's body, cord blood offers other advantages over **bone marrow transplantation**. It is relatively quick and easy to thaw the cord blood and infuse it, while bone marrow harvesting is an invasive procedure with risks to the donor. In addition, cord blood is less likely to be contaminated with viruses that may create complications for the recipient.

Considerations in deciding to bank cord blood

Although the list of diseases treated with umbilical cord stem cells is impressive and growing, controversy exists about whether parents should pay private cord cell banks to preserve their newborn's blood. Private cord cell banks sell their services as a type of "insurance." In case the child develops a treatable disease, the child's own stem cells will be a perfect match. However, if the disease is caused by a genetic defect, (e.g., sickle cell and other **anemias**) the child's own stem cells will be useless, because they will contain the same genetic defect. In addition, the quantity of cord blood that can be collected is only enough to treat a child. Although research is being done to try to multiply cord cells in the laboratory in quantities great enough to treat an adult, results have not been successful. Therefore, if an adult develops a treatable disease, even if his own cord blood was banked, the quantity will be insufficient to produce a cure. Also, cord blood storage is a new enough technology that it is not clear how long the blood can remain frozen and still be effective.

In its statement on cord blood banking, the American Academy of Pediatrics concluded:

- There are no good estimates of how often a child will need a transplant of his own cells. Estimates range from 1 in 1,000 to 1 in 200,000
- Certain genetic disorders are not cured by autologous transplants
- Parents should be encouraged to donate their child's cord blood to free public cord blood banks for the widest possible use rather than paying private companies to store cord blood

The American College of Obstetricians and Gynecologists supports the position that parents should not be sold private blood cord banking without a realistic assessment of their need, nor should parents feel guilty if they are not eager or able to meet the annual expense associated with private storage. Although cord blood collection is safe, unless there is a family history of diseases for which hematopoietic stem cells are helpful, most pediatricians and obstetricians feel private cord blood storage is an unnecessary expense.

KEY TERMS

Allogeneic—A transplant where the donated material comes from a different (although often related) individual than the recipient.

Autologous—A transplant where the material for the transplant comes from the individual who is also the recipient; thus, the transplant material is genetically identical to the donor's body.

Hematopoietic stem cell—A cell that can develop into any type of specialized blood cell.

Precautions

Umbilical cord blood collection is usually not done in the case of multiple births.

Description

Cord blood collection is a simple procedure that takes between three and seven minutes. It is done immediately after the baby is delivered. Cord blood is drained into a standard blood bag and then processed and frozen at very low temperatures.

Preparation

Parents who wish to bank their child's cord blood must plan ahead. Private storage requires ordering a kit in advance and coordinating with the healthcare providers doing the delivery to make sure the cord blood is collected properly. Mothers must test negative for infectious diseases, such as HIV and hepatitis, before delivery. Donation to a public cord blood bank is not always possible because of their limited number and location.

Aftercare

No special aftercare is required for mother or child, but the cord blood must remain frozen at low temperatures.

Risks

The main risk associated with umbilical cord blood collection is the possibility that it will become contaminated with bacteria during collection.

Parents who are interested in private cord blood storage should research the company with which they contract, just as they would in making any business decision. They need to know the costs, whether the annual fee can increase, and what will happen to the blood if the company goes out of business.

Umbilical hernia repair

Definition

An umbilical **hernia repair** is a surgical procedure performed to fix a weakness in the abdominal wall or to close an opening near the umbilicus (navel) that has allowed abdominal contents to protrude. The abdominal contents may or may not be contained within a membrane or sac. The medical name for a **hernia** repair is herniorrhaphy.

Purpose

Umbilical hernias are usually repaired either to relieve discomfort or to prevent complications. It is not always necessary to fix an umbilical hernia. If the person is not in **pain**, the hernia is often not repaired. Complications may develop if pressure inside the abdomen resulting from daily activity pushes the abdominal

WWW.BOOKBAZ.IR

contents further through the opening. They may then become twisted or strangulated. Strangulation is a condition in which the circulation to a section of the intestine (or other part of the body) is cut off by compression or constriction; it can cause extreme pain. If the strangulation persists, the tissue can die from lack of blood supply and lead to an infection.

Demographics

An umbilical hernia can occur in both men and women and can occur at any age, although it is often present at birth. Umbilical hernias are found in about 20% of newborns, especially in premature infants. Umbilical hernias are more common in male than in female infants; with regard to race, they are eight times more common in African Americans than in Caucasians or Hispanics. While umbilical hernia is not a genetically determined condition, it tends to run in families. In the adult population, umbilical hernias are more common in overweight persons with weak abdominal muscles and in women who are either pregnant or have borne many children. People with **liver disease** or fluid in the abdominal cavity are also at higher risk of developing an umbilical hernia.

Description

Repair of an abdominal hernia involves a cut, or incision, in the umbilical area. Most herniorrhaphies take about two hours to complete. After the patient has been given a sedative, the anesthesiologist will administer a local, spinal, or general anesthetic. The type of **anesthesia** used depends on the patient's age, general health, and complexity of the procedure. The incision is usually made underneath the belly button. The herniated tissues are isolated and pushed back inside the abdominal cavity. A hernia repair may be done using traditional open surgery or with a laparoscope. A laparoscopic procedure is performed through a few very small incisions. The hole in the abdominal wall may be closed with sutures, or by the use of a fine sterile surgical mesh. The mesh provides additional strength. Some surgeons may choose to use the mesh when repairing a larger hernia. A hernia repair done with a mesh insert is called a tension-free procedure because the surgeon does not have to put tension on the layer of muscle tissue in order to bring the edges of the hole together.

Diagnosis/Preparation

Diagnosis

In children, umbilical hernias are often diagnosed at birth, usually when the doctor feels a lump in the area around the belly button. The hernia may also be diagnosed if the child is crying from pain, because the crying will increase the pressure inside the abdomen and make the hernia more noticeable.

Umbilical hernias in adults occur more often in pregnant women and obese persons with weak stomach muscles. They may develop gradually without producing any discomfort, but the patient may see a bulge in the abdomen while bathing or getting dressed. Other patients consult their doctor because they have felt the tissues in the abdomen suddenly give way when they are having a bowel movement. In an office examination, the patient may be asked to lie down, lift the head, and **cough**. This action increases pressure inside the abdomen and causes the hernia to bulge outward.

A hernia that has become incarcerated or strangulated is a medical emergency. Its symptoms include:

- nausea
- vomiting
- abdominal swelling or distension
- pale complexion
- weakness or dizziness
- extreme pain

KEY TERMS

Abdominal distension—Swelling of the abdominal cavity, which creates painful pressure on the internal organs.

Hernia—The protrusion of a loop or piece of tissue through an incision or abnormal opening in other tissues.

Herniorraphy—The medical name for a hernia repair procedure.

Incarceration—The abnormal confinement of a section of the intestine or other body tissues. An umbilical hernia may lead to incarceration of part of the intestine.

Intra-abdominal pressure—Pressure that occurs within the abdominal cavity. Pressure in this area builds up with coughing, crying, and the pressure exerted when bearing down with a bowel movement.

Strangulation—A condition in which a vessel, section of the intestine, or other body part is compressed or constricted to the point that blood cannot circulate.

Umbilicus—The area where the umbilical cord was attached; also known as the navel or belly button.

When a hernia is present at birth, some surgeons may opt for a "wait and see" approach, as umbilical hernias in children often close by themselves with time. If the hernia has not closed by the time the child is three or four years old, then surgery is usually considered. If the hernia is very large, surgery may be recommended.

Repair of an umbilical hernia in an adult is usually considered elective surgery. The patient's surgeon may recommend the procedure, however, on the grounds that hernias in adults do not close by themselves and tend to grow larger over time.

Preparation

Adults scheduled for a herniorraphy are given standard blood tests and a **urinalysis**. They should not eat breakfast on the morning of the procedure, and they should wear loose-fitting, comfortable clothing that they can easily pull on after the surgery without straining their abdomen.

Aftercare

Aftercare will depend in part on the invasiveness of the surgery, whether laparoscopic or open; the type of anesthesia; the patient's age; and the person's general medical condition. Immediately after the procedure, the person will be taken to the recovery area of the surgical center, where nurses will monitor the patient for signs of excessive bleeding, infection, uncontrolled pain, or **shock**. Hernia repairs are usually performed on an outpatient basis, which means that the patient can expect to go home within a few hours of the surgery. Adult patients, however, should arrange to have a friend or relative drive them home. If possible, someone should stay with them for the first night.

The nurses will provide the patient with instructions on incision care. The specific instructions will depend on the type of surgery and the way in which the incision was closed. Sometimes a see-through dressing is placed on the wound that the patient can remove about three days after the procedure. It may be necessary to keep the dressing dry until some healing has taken place. Very small incisions may be closed with Steri-strips rather than sutures.

Risks

There are surgical and anesthesia-related risks with all surgical procedures. The primary surgical risks include bleeding and infection. Anesthesia-related risks include reactions to the specific anesthetic agents that are used; interactions with over-the-counter and herbal preparations; and respiratory problems. The greatest risk associated with umbilical hernia is missing the diagnosis. Additional risks include the formation of scar tissue and recurrence of the hernia.

Results

Umbilical hernia repair is usually considered an uncomplicated procedure with a relatively short recovery period. A study reported in the December 2002 issue of the *American Journal of Surgery* found that patients who had laparoscopic surgery with the use of a surgical mesh had fewer complications and reoccurrences of a hernia than those with the traditional open surgery. However, laparoscopic surgery took somewhat longer to perform, possibly because the laparoscopic approach is often used for larger repairs.

Morbidity and mortality rates

In general, there are few complications with hernia repair in children. The most serious complication is surgical injury to the bladder or intestine; fortunately, this complication is very rare—about one in 1,000 patients. The recurrence rate is between 1% and 5%; recurrence is more likely in patients with very large hernias. The rate of infection is less than 1%. In the adult population, a November 2001 study reported in the *American Journal of Surgery* found a 5% mortality in elderly patients undergoing emergency hernia repairs.

Undernutrition

Definition

Undernutrition is the result of inadequate intake of calories, protein, or micronutrients. Although undernutrition and **malnutrition** often are used interchangeably, malnutrition is a more inclusive term that includes overnutrition.

Demographics

The United Nations Children's Fund (UNICEF) estimates that about 195 million children have stunted growth as a direct result of undernutrition. Of these, about 90% are in Africa and Asia. India has the largest absolute number of stunted children, while Afghanistan has the highest percentage of stunted children. Undernutrition is uncommon in the developed world, but the British **Nutrition** Foundation estimates that about two million people in the United Kingdom are undernourished. Undernutrition has the most severe impact on children under age five.

Undernutrition in children is much less common in the United States than in developing countries. Estimates suggest that only about 1% of all children in the United States experience undernutrition. The highest risk children in the United States are those living in homeless shelters, where an estimated 10% of children are undernourished. Estimates also suggest that one in every seven elderly individuals in the United States consume fewer than 1,000 calories per day and are undernourished.

Description

Undernutrition is a serious problem in developing countries, especially in children under age five years. Undernutrition can begin before a baby is born. Deficiencies in calories, protein, **minerals**, and/or **vitamins** often affect the fetus during **pregnancy** because the mother does not consume enough calories and micronutrients. This often results in the delivery of a low birthweight baby. According to the World Health Organization (WHO), low birthweight accounts for about 60% of deaths in newborns in developing countries or 3.3% of all child deaths.

Undernutrition frequently continues into early childhood. There is a strong relationship between undernutrition and failure to survive. Children may not directly starve to death from undernutrition, although some do die of disorders such as marasmus, which is a severe deficiency in calories and protein. Instead, undernourished children tend to have weak immune systems that leave them highly susceptible to common diseases such as **diarrhea**, **pneumonia**, **malaria**, and **measles**, all of which are common in the developing world. Often, undernourished children go through a downward cycle of repeated disease and recovery before they die; if they do survive, this cycle exacts a heavy toll on their development. Exact figures are difficult to obtain from developing countries, but estimates suggest that maternal and child undernutrition is the cause of 3–5 million deaths annually. Zinc and **vitamin A** deficiency are the most common micronutrient deficiencies, while iron and iodine deficiencies also contribute to undernutrition.

A critical window for development exists between birth and age two years. Even when children survive these critical years, the effects of undernutrition remain. Often these children are stunted (short stature) or wasted (seriously underweight). In addition to physical effects, undernutrition can restrict a child's mental development.

Undernutrition in the elderly is a greater problem in the United States than undernutrition in children. Declining appetite, limited funds, difficulty in preparing and eating food, and disease all contribute to undernutrition in the elderly. Elderly people living in nursing homes or hospitalized for prolonged periods are at high risk for undernutrition. Any age individuals who have had **gastric bypass** surgery may experience undernutrition unless they take prescribed vitamin and mineral supplements.

Risk factors

Risk factors for undernutrition include inadequate food supply (e.g., famine), inadequate variety of food (i.e., food does not contain all the required micronutrients), living in a war zone, poverty, low maternal status, poor **breastfeeding** habits, and cultural attitudes (e.g., boy infants may be fed more than girl infants).

Homelessness is a major cause of undernutrition in the United States, as is **alcoholism**. Diseases such as depression or other mental illness can cause individuals to stop eating or to refuse to eat a variety of foods. Certain medications can also inhibit the uptake of nutrients from the digestive system, resulting in undernutrition. Certain diseases, such as some cancers and **AIDS**, can cause the body to increase the amount of calories used, resulting in severe wasting, called cachexia.

KEY TERMS

Micronutrients—Minerals and vitamins needed in small quantities to maintain health (e.g., iodine).

Stunting—A height more than two standard deviations from the median height for the age in the reference population.

Wasting—Weight more than two standard deviations below that of the median weight for the reference population.

Causes and symptoms

The root cause of undernutrition is inadequate intake of calories, protein, and micronutrients. Secondary causes are the same as the risk factors previously described.

Symptoms of undernutrition in children include low birth weight, stunting, wasting, low energy level, slowed physical development, impaired mental development, and frequent serious illnesses. In the elderly, undernutrition can cause weight loss, thinning and drying of the skin, hair loss, constantly feeling cold, confused thinking, frequent falls, and frequent infections. These symptoms often go unrecognized and are attributed to a general decline due to **aging**.

Diagnosis

Examination

Diagnosis is most often made by examination and by comparing the height and weight of the individual to the median height and weight of the reference population. The physician will review drugs the individual is taking and ask questions about alcohol and food consumption.

Tests

A **complete blood count** (CBC) generally is done to assess the individual's general health and to look for signs of infections. Blood tests may be done to measure the amount of albumin in the blood. Albumin is a blood protein that decreases when there is an inadequate amount of protein in the diet. Additional tests may be done when a specific vitamin or **mineral deficiency** is suspected.

Treatment

The only treatment for undernutrition is to increase calories and protein and to replace the micronutrients missing from the diet. In healthcare settings, such as a nursing home or hospital, this can be done in consultation with a registered dietitian. Long-term success in reducing undernutrition generally requires overcoming the barriers that prevent the individual from getting enough calories and enough food variety. This may involve:

- treating any underlying disease or mental condition contributing to the undernutrition
- overcoming barriers to food preparation, for example by enrolling the individual in Meals on Wheels
- providing a wide range of nutritious food through meals for the homeless, the establishment of inner city farmers's markets, or providing transportation to local food banks
- using drugs to stimulate the appetite
- enrolling individuals in food support programs such as Women Infants and Children (WIC), the Supplementary Nutrition Program (SNAP, formerly food stamps), and the Federal School Lunch program in the United States

Individuals who cannot eat, for example those who cannot swallow because they have had a **stroke**, may be fed through a tube inserted into the nose and down the esophagus to the stomach. Individuals who do not absorb enough nutrients from the digestive tract may be fed intravenously (total **parenteral nutrition**). Both these feeding methods have drawbacks and potentially serious side effects.

Prognosis

Some early effects of undernutrition cannot be reversed. Consistent undernutrition before birth and during the first five years of life often leads to childhood death. In survivors, it has permanent physical and developmental effects. Even if the child later receives adequate nutrition, he or she may remain short of stature and have permanent cognitive deficits. Undernutrition during pregnancy can lead to **miscarriage**, premature delivery, a low birthweight baby, maternal susceptibility to disease, and maternal death. Undernutrition in the elderly results in more frequent and more severe illness and infection.

Prevention

The problem of preventing undernutrition is complex. Many international aid agencies work to prevent undernutrition, especially undernutrition in children. Their goal is to eventually help developing countries develop adequate food resources for the

WWW.BOOKBAZ.IR

entire population. To do this, they must overcome food delivery, storage, and distribution problems; regional warfare; poverty; illiteracy; and cultural attitudes. UNICEF and WHO have made reducing child undernutrition one of their priorities for the twenty-first century.

Exclusive breastfeeding for at least six months with supplemental breast feeding until age two is recommended for all babies. This is especially important in developing countries where supplies of clean water and adequate infant food are limited. According to WHO, appropriately breastfed children in developing countries are six times more likely to survive to age five than those who are not breast fed.

In the United States, treating homelessness, alcoholism, and drug abuse, as well as educating individuals about food security programs that are available to them, are the most effective ways of preventing undernutrition.

Undescended testes

Definition

Also known as cryptorchidism, undescended testes is a congenital condition characterized by testicles that do not extend to the scrotum. This condition is the most common male sexual development abnormality.

Demographics

Thirty percent of premature boys have testes that have not yet made the full descent. Only 3–5% of full-term baby boys have undescended testes, and half of those complete the journey by the age of four months. Most cases, about 97% to 99%, of undescended testes naturally correct themselves during the first year of life. Spontaneous descent, however, does not seem to occur after age 9 months.

Description

In the fetus, the testes are in the abdomen. As development progresses they migrate downward through the groin and into the scrotum. This event takes place late in fetal development, during the eighth month of gestation. Undescended testes that are not corrected can lead to sterility, **testicular torsion** and an increased risk of **testicular cancer**.

Causes and symptoms

The cause of undescended testes is presently unknown. However, its symptoms are quite apparent. One or both of the testicles can be undescended, therefore the testicles appear to be either missing or lopsided.

Undescended testicles are more likely to occur in boys of low birth weight, from twin pregnancies, and in small babies. Maternal estrogen exposure seems to

play a role in cryptorchidism. Cryptorchidism is also associated with the following conditions:

- inguinal hernia
- hypospadias
- cerebral palsy
- intellectual disability (ID) and Down syndrome
- Wilms tumor
- prune belly syndrome and Prader-Willi syndrome

Diagnosis

Examination

The newborn examination always includes checks for testes in the scrotum. It they are not found, a search will be conducted, but not necessarily right away. In most cases, the testes will drop into place later. If the testes are present at all, they can be anywhere within a couple of inches of the appropriate spot. In 5% of cases, one testis is completely absent. In 10%, the condition occurs on both sides.

The patient should be examined in a warm location and should be as relaxed as possible. The examination begins with a visual inspection prior to manual palpation. The patient may be placed in the frog-leg or catcher position to facilitate the examination. The preferred examination technique is to begin palpating at the level of the inguinal canal and to perform a milking motion down until the level of the scrotum. If the testicle cannot be located in the inguinal area, examination of the penis, femoral and perineal areas are conducted as occasionally the testicle may be found in those locations.

Tests

If the testes are unable to be palpated or if there is unilateral or bilateral undescended testes, chromosomal testing and measurement of multiple hormone levels may be indicated.

Procedures

Diagnostic **laparoscopy** may be implemented for localizing testis which can not be palpated. This procedure is often combined with definitive therapy such as laparoscopic or open **orchiopexy**.

Treatment

Once it is determined that the testes will not naturally descend, surgery becomes necessary. The procedure is called an orchiopexy and is relatively simple once the testes are located. The surgery is usually performed when the boy is between one and two years old. Early surgical intervention, prior to age one, seems to be of most benefit.

In Europe, hormonal therapy, utilizing human chorionic gonadotropin and/or leuteinizing releasing hormones, has been used for many years to treat cryptorchidism especially in patients who may not be candidates for surgical intervention.

Prognosis

Orchiopexy conducted prior to age two years has been shown to result in less damage to the testis and may also improve viability of sperm. Currently, orchiopexy prior to age 1 is recommended.

In men with undescended testes the risk for developing testicular cancer is 3–5% which is 4 to 7 times higher than when compared to the risk for men without this condition. Surgical intervention does not protect against the development of subsequent testicular cancer but it does place the testis in a more accessible anatomical position to facilitate routine self-evaluation and for clinical evaluation purposes.

Men with a history of bilateral undescended testicles tend to have a higher **infertility** rate when compared to men with unilateral cryptorchidism or with men in the general population. Men with bilateral undescended testicles have a 60% paternity rate while men with a unilateral undescended testicle have 90% paternity rate as compared to the paternity rate of 94% of men in the general population.

Upper GI exam

Definition

An upper GI examination is an examination that produces pictures or scans of the upper gastrointestinal tract, including the esophagus, stomach, and upper small intestine (duodenum).

Description

The two most common forms of upper GI exam are the upper GI series and the capsule **endoscopy**. The upper GI series uses ingested barium, a radioactive substance, to image the upper GI system. The capsule endoscopy is a upper GI exam during which the patient swallows a very small camera contained inside a capsule that captures and transmits pictures as it moves through the upper GI tract.

Upper GI series

An upper GI series takes place in a hospital or clinic setting and is performed by an x-ray technician and a radiologist. A radiologist typically is in attendance to oversee the procedure and view and interpret the fluoroscopic pictures. Before the test begins, the patient is sometimes administered an injection of glucagon, a medication that slows stomach and bowel activity, to allow the radiologist to get a clearer picture of the gastrointestinal tract. In order to further improve the clarity of the upper GI pictures, the patient may be given a cup of baking soda crystals to swallow, which distend the stomach by producing gas.

Once these preparatory steps are complete, the patient stands against an upright x-ray table, and a fluoroscopic screen is placed in front of the person. The patient is then asked to drink from a cup of flavored barium sulfate, a thick and chalky-tasting liquid that allows the radiologist to see the digestive tract, while the radiologist views the esophagus, stomach, and duodenum on the fluoroscopic screen. The patient is asked to change positions frequently in order to coat the entire surface of the gastrointestinal tract with barium. The technician or radiologist may press on the patient's abdomen in order to spread the barium. The x-ray table will also be moved several times throughout the procedure. The radiologist will ask the patient to hold his breath periodically while exposures are being taken. The entire procedure takes approximately 30 minutes.

In some cases, in addition to the standard upper GI series, a doctor may request a detailed intestine, or small bowel, radiography and fluoroscopy series; it is also called a small bowel follow-through (SBFT). Once the preliminary upper GI series is complete, the patient is escorted to a waiting area while the barium travels down through the rest of the small intestinal path. Every 15–30 minutes, the patient returns to the x-ray suite for additional x rays or films. Once the barium has completed its trip down the small bowel tract, the test is completed. This procedure can take from one to four hours.

Esophageal radiography, also called a barium esophagram or a barium swallow, is a study of the esophagus only and is usually performed as part of the upper GI series. It is commonly used to diagnose the cause of difficulty in swallowing (dysphagia) and for detecting **hiatal hernia**. A barium sulfate liquid, and sometimes pieces of food covered in barium, are given to the patient to drink and eat while a radiologist examines the swallowing mechanism on a fluoroscopic screen. The test takes approximately 30 minutes.

Capsule endoscopy

A capsule endoscopy begin in a doctor's office, hospital, or clinic, when the patient is given the capsule containing the camera to swallow. The capsule is usually the size of a large multivitamin pill, and most patients do not have serious problems swallowing it. The patient is fitted with receivers attached to the chest and a recording device that is generally worn strapped around the waist or over the shoulder.

The camera inside the capsule takes thousands of color images during its journey through the GI tract. These pictures are then transmitted and recorded so that they can be examined by the patient's medical team. In most cases, the patient can go about normal daily activities while the camera is moving through the

GI tract. Some patients who have highly physical jobs may be asked not to work the day of the exam.

Most capsule endoscopy cameras record photographs for eight to twelve hours. After this time, the patient can remove the receivers and return them to the doctor or hospital so that the images can be retrieved and reviewed. In most cases, the capsule containing the cameras evacuates from the body during a normal bowel movement. The camera can be flushed down the toilet.

Purpose

An upper GI series is frequently requested when a patient experiences unexplained symptoms of abdominal **pain**, difficulty in swallowing (dysphagia), regurgitation, **diarrhea**, or weight loss. It is used to help diagnose disorders and diseases of, or related to, the upper gastrointestinal tract, including cases of hiatal **hernia**, diverticuli, **ulcers**, tumors, obstruction, enteritis, **gastroesophageal reflux disease**, Crohn's disease, and pulmonary aspiration.

Precautions

Because of the risks of radiation exposure to the fetus, pregnant women are advised to avoid any procedures involving radioactive materials, including barium (a radioactive substance used to show contrast in the images). Patients with an obstruction or perforation in their bowel should not ingest barium for an upper GI exam but may still be able to undergo the procedure if a water-soluble contrast medium is substituted for the barium. Individuals with difficulty swallowing should not have a capsule endoscopy.

Glucagon, a medication sometimes given prior to an upper GI procedure, may cause nausea and **dizziness**.

Preparation

Patients must not eat, drink, or smoke for eight hours prior to undergoing an upper GI examination. Longer dietary restrictions may be required, depending on the type and diagnostic purpose of the test. Patients undergoing a small bowel follow-through exam may be asked to take **laxatives** the day prior to the test. Upper GI patients are typically required to wear a hospital gown or similar attire and to remove all jewelry, so the camera has an unobstructed view of the abdomen.

Aftercare

No special aftercare treatment or regimen is required for an upper GI series. The patient may eat and drink as soon as the test is completed. The barium sulfate may make the patient's stool white for several days, and patients having a capsule endoscopy are encouraged to drink plenty of fluids in order to eliminate the capsule from their system. Patients who do not see the capsule evacuate in a few days after a capsule endoscopy should alert their doctor so that it can be assured it did not become lodged in the body.

KEY TERMS

Dysphagia—Difficulty in swallowing, as if something is stuck in the throat.

Gastroesophageal reflux—A condition in which the stomach contents back up into the esophagus. Because the stomach contents are highly acidic, this can cause irritation and heartburn.

Hiatal hernia—A condition in which part of the stomach protrudes through a hole in the diaphragm next to the esophagus.

Results

A normal upper GI series or capsule endoscopy will show a healthy, functioning, and unobstructed digestive tract.

Abnormal results

Obstructions or inflammation, including ulcers of the esophagus, stomach, or small intestine, or irregularities in the swallowing mechanism are just a few of the possible abnormalities that may show up on an upper GI series or capsule endoscopy.

Risks

Because the upper GI series is an x-ray procedure, it does involve minor exposure to ionizing radiation. Unless the patient is pregnant or multiple radiological or fluoroscopic studies are required, the small dose of radiation incurred during a single procedure poses little risk. However, multiple studies requiring fluoroscopic exposure that are conducted in a short time period have been known, on rare occasions, to cause skin death (necrosis) in some individuals. This risk can be minimized by careful monitoring and documentation of cumulative radiation doses administered to these patients. There are few risks to a capsule endoscopy for patients who have normal swallowing. In very rare cases the capsule may become lodged in the GI tract and require surgical removal.

Urea clearance by the kidneys *see* **Kidney function tests**

Ureteral stenting

Definition

Ureteral stents are thin catheters threaded into segments of the ureter that carry urine, produced by the kidney, either down into the bladder internally, or to an external collection system. Insertion is most often done through the skin (percutaneously); however, in the presence of kidney or ureteral stones, stenting is ideally done during **cystoscopy**.

KEY TERMS

Cystoscopy—Examination or treatment of the interior of the urinary bladder by looking through a special instrument with reflected light.

Stricture—An abnormal narrowing of a tube or passageway.

Ureter—The tube-like passageway in the body that carries urine from the kidney to the bladder.

Purpose

Ureteral stenting may be placed on a long-term basis (months to years) in order to bypass ureteral obstruction. Short-term stenting (weeks to months) may be used as an adjunct to open surgical procedures of the urinary tract to provide a mold around which healing can occur, or to divert the urinary flow away from areas of leakage. Following balloon dilation or incision of ureteral strictures, placement of stents maintains the functionality of the ureters. Stents may also be used in the presence of **kidney stones** to manipulate or prevent stone migration prior to treatment or to make the ureters more easily identifiable during difficult surgical procedures. Ureteral stents may be used in those with active kidney infection or with markedly diseased, intolerant bladders (e.g., damage from **radiation therapy**, bladder invasion by adjacent neoplasm).

Preparation

The procedure should be thoroughly explained by a medical professional before it takes place. The patient will be asked to put on a hospital gown. If the procedure is performed with the aid of a cytoscope, the patient will assume a position that is typically used in a gynecological exam.

Aftercare

Stents must be periodically replaced to prevent **fractures** within the catheter wall or buildup of encrustation. Stent replacement is recommended approximately every six months or more often in patients who form stones.

Results

Normally, a ureteral stent assures the patient of a free flow of urine. Postoperatively, urine flow will be monitored to ensure the stent has not been dislodged or obstructed.

Abnormal results

Serious complications of the procedure occur in approximately four percent of cases, with minor complications in another 10%. These may include:

- Bleeding. Usually minor and easily treated, occasionally requiring transfusion
- Catheter migration or dislodgement. May require readjustment with the fluoroscope in the Radiology Department
- Coiling of the stent within the ureter. May cause lower abdominal pain or flank pain on urination, urinary frequency, or blood in the urine
- Introduction or worsening of infection
- Penetration of adjacent organs (e.g., bowel, gallbladder, or lungs)

Urethritis

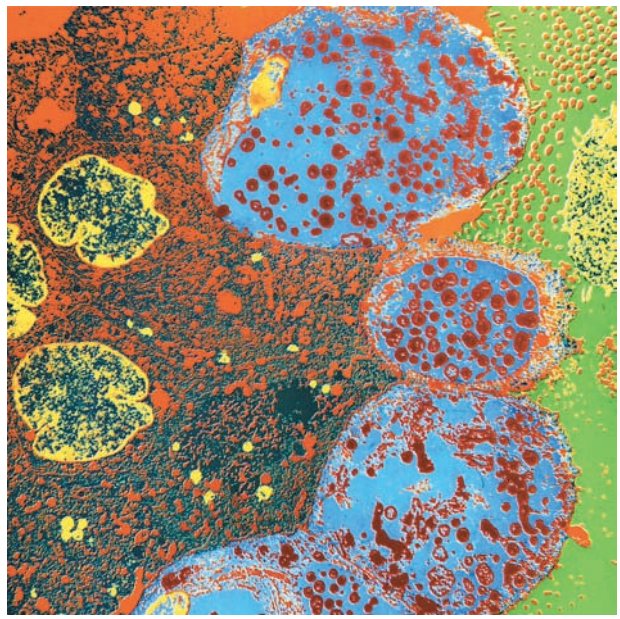
Definition

Urethritis is an inflammation of the urethra that is usually caused by an infection.

Description

The urethra is the canal that moves urine from the bladder to the outside of the body. When this canal becomes infected, inflammation occurs due to the accumulation of white blood cells in the area. When this occurs, it is called urethritis. Besides the urethra, the urinary tract consists of the bladder, ureters, and kidneys. Inflammation can move up the urethra, causing **cystitis** in the bladder, or **nephritis** in the kidneys. Collectively, these inflammations are called urinary tract infections or UTIs.

Urinary tract infections are much more common in women than in men, probably due to anatomy.



A false color transmission electron micrograph (TEM) scan of non-specific urethritis. *(Custom Medical Stock Photo, Inc.)*

Infections are especially more common in older women, due to bladder problems.

Causes and symptoms

Uncomplicated urethritis usually results from infection by the bacteria *Escherichia coli*, commonly found in the bowel. Complicated urethritis can occur when other problems exist, such as **kidney stones**, malformations of the urinary tract, **spinal cord injury**, or a compromised immune system. People with diabetes tend to have more urinary tract infections, as well as hospitalized patients. Urinary tract infections can also be sexually transmitted. Some people seem to be susceptible to urinary tract infections, having them recurrently.

Frequently, a **urinary tract infection** has no symptoms. Common symptoms though, include **pain** and a burning sensation when urinating, frequent urination, or passing blood in the urine. Signs that the infection may be worsening include **fever** and chills, nausea, **vomiting**, and lower back pain.

Diagnosis

The diagnosis for a urinary tract infection is made by assessing the symptoms, feeling (palpating) the abdomen for tenderness, and a **urinalysis**. A urinalysis, or urine sample, is examined for both the presence of bacteria and white blood cells. After this, a **urine**

WWW.BOOKBAZ.IR

culture to determine what bacteria is causing the infection may be done.

Treatment

Typical treatment for urinary tract infections is a course of **antibiotics**. In women who have recurrent urethritis, the diagnosis and treatment is often resolved over the phone. Additional drugs are sometimes given to relieve discomfort.

Alternatives

For those individuals who seem to be more susceptible to urinary tract infections, drinking lots of fluids at the first sign of an infection can ward it off by diluting the bacteria present and flushing the system. Adding a teaspoon of baking soda to a glass of water and drinking it can change the pH of the urine, causing it to burn less. Also, cranberry juice contains a compound that can prevent bacteria from sticking to and thus growing in the urinary tract. Antimicrobial herbs, such as uva ursi (*Arctostaphylos uva-ursi*) and pipsissewa (*Chimaphila umbellata*), may be helpful. Other herbs, such as marsh mallow (*Althaea officinalis*), slippery elm (*Ulmus fulva*), comfrey (*Symphytum officinale*), plantain (*Plantago major*), and cornsilk, can soothe the urinary tract. *Lactobacillus acidophilus* and *L. bifidus* supplementation reintroduces normal flora into the urinary tract. **Acupuncture** and homeopathy can also be effective therapies for urethritis.

Prognosis

Given the appropriate antibiotic, urinary tract infections usually go away quickly. If not treated soon enough, however, urethritis can move up the urinary tract, infecting the bladder and possibly the kidneys, resulting in kidney damage. If the infection moves into the blood, additional complications can arise. Those who have previously had a urinary tract infection are more susceptible to additional urinary tract infections. Because of this, patients need to be aware of the symptoms so that a physician can be notified if the infection becomes recurrent.

Prevention

There are some steps that can be taken to keep the urinary tract healthy and prevent infection:

- drink plenty of fluids
- do not hold urine once the urge to urinate has occurred
- after a bowel movement, wipe from front to rear to keep bowel bacteria at a distance
- wear cotton underwear
- rinse soap off well in the shower
- urinate after sexual intercourse
- for post-menopausal women, estrogen replacement therapy can help prevent urinary tract infection

Uric acid tests

Definition

Uric acid tests are tests that are done to measure the levels of uric acid in blood serum or in urine.

Purpose

Uric acid tests are used to evaluate the blood levels of uric acid for **gout** and to assess uric acid levels in the urine for kidney stone formation. The urine test is used most often to monitor patients already diagnosed with **kidney stones**, but it can also be used to detect disorders that affect the body's production of uric acid and to help measure the level of kidney functioning.

Uric acid is a waste product that results from the breakdown of purine, a nucleic acid. (Nucleic acids are the building blocks of DNA.) Uric acid is made in the liver and excreted by the kidneys. If the liver produces too much uric acid or the kidneys excrete too little, the patient will have too much uric acid in the blood. This condition is called hyperuricemia. Supersaturated uric acid in the urine (uricosuria) can crystallize to form kidney stones that may block the tubes that lead from the kidneys to the bladder (the ureters).

Precautions

Blood test

Patients scheduled for a blood test for uric acid should be checked for the following medications: loop **diuretics** (Diamox, Bumex, Edecrin, or Lasix); ethambutol (Myambutol); vincristine (Oncovin); pyrazinamide

(Tebrazid); thiazide diuretics (Naturetin, Hydrex, Diuril, Esidrix, HydroDiuril, Aquatensen, Renese, Diurese); **aspirin** (low doses); **acetaminophen** (Tylenol); ascorbic acid (vitamin C preparations); levodopa (Larodopa); or phenacetin. These drugs can affect test results.

Certain foods that are high in purine may increase the patient's levels of uric acid. These include kidneys, liver, sweetbreads, sardines, anchovies, and meat extracts.

Urine test

Patients should be checked for the following medications before the urine test: diuretics, aspirin, pyrazinamide (Tebrazid), phenylbutazone, probenecid (Benemid), and allopurinol (Lopurin). If the patient needs to continue taking these medications, the laboratory should be notified.

The laboratory should also be notified if the patient has had recent x ray tests requiring contrast dyes. These chemicals increase uric acid levels in urine and decrease them in blood.

Description

The uric acid blood test is performed on a sample of the patient's blood, withdrawn from a vein into a vacuum tube. The procedure, which is called a venipuncture, takes about five minutes. The urine test requires the patient to collect all urine voided over a 24-hour period, with the exception of the very first specimen. The patient keeps the specimen container on ice or in the refrigerator during the collection period.

Preparation

The uric acid test requires either a blood or urine sample. For the blood sample, the patient should be **fasting** (nothing to eat or drink) for at least eight hours before the test. The urine test for uric acid requires a 24-hour urine collection. The urine test does *not* require the patient to fast or cut down on fluids. Some laboratories encourage patients to drink plenty of fluids during the collection period.

Risks

Risks for the blood test are minimal, but may include slight bleeding from the puncture site, a small bruise or swelling in the area, or **fainting** or feeling lightheaded.

Results

Blood test

Reference values for blood uric acid vary from laboratory to laboratory but are generally found within the following range: Male: 2.1–8.5 mg/dL; female: 2.0–6.6 mg/dL. Values may be slightly higher in the elderly.

KEY TERMS

Fanconi's syndrome—A rare disorder caused by vitamin D deficiency or exposure to heavy metals.

Gout—A metabolic disorder characterized by sudden recurring attacks of arthritis caused by deposits of crystals that build up in the joints due to abnormally high uric acid blood levels. In gout, uric acid may be overproduced, underexcreted, or both.

Hyperuricemia—Excessively high levels of uric acid in the blood, often producing gout.

Purine—A white crystalline substance that is one of the building blocks of DNA. Uric acid is produced when purine is broken down in the body.

Uric acid—A compound resulting from the body's breakdown of purine. It is normally present in human urine only in small amounts.

Uricosuria—Increased levels of uric acid in the urine.

Wilson's disease—A rare hereditary disease marked by the buildup of copper in the liver and brain, causing loss of kidney function.

Urine test

Reference values for 24-hour urinary uric acid vary from laboratory to laboratory but are generally found within the following range: 250–750 mg/24 hours.

Abnormal results

The critical value for the blood test is a level of uric acid higher than 12 milligrams per deciliter (about 3.4 ounces).

Increased *production* of uric acid may result from eating foods that are high in purine. Increased uric acid levels due to overproduction may also be caused by gout, by a genetic disorder of purine metabolism, or by metastatic cancer, destruction of red blood cells, leukemia, or cancer **chemotherapy**.

Decreased *excretion* of uric acid is seen in chronic **kidney disease**, low thyroid, toxemia of **pregnancy**, and **alcoholism**. Patients with gout excrete less than half the uric acid in their blood as other persons. Only 10-15% of the total cases of hyperuricemia, however, are caused by gout.

WWW.BOOKBAZ.IR

Abnormally low uric acid levels may indicate that the patient is taking allopurinol or probenecid for treatment of gout; may be pregnant; or suffers from Wilson's disease or Fanconi's syndrome.

Urinalysis

Definition

A urinalysis is a group of manual and/or automated qualitative and semi-quantitative tests performed on a urine sample. It is also known as routine and microscopy (R&M). A routine urinalysis usually includes the following tests: color, transparency, specific gravity, pH, protein, glucose, ketones, blood, bilirubin, nitrite, urobilinogen, and leukocyte esterase. Some laboratories include a microscopic examination of urinary sediment with all routine urinalysis tests. If not, they customarily perform the microscopic exam if transparency, glucose, protein, blood, nitrite, or leukocyte esterase is abnormal.

Purpose

Routine urinalyses are performed for several reasons:

- general health screening to detect renal and metabolic diseases
- diagnosis of diseases or disorders of the kidneys or urinary tract
- monitoring of patients with diabetes

In addition, quantitative urinalysis tests may be performed to help diagnose many specific disorders, such as endocrine diseases, **bladder cancer**, **osteoporosis**, and **porphyrias** (a group of disorders caused by chemical imbalance). Quantitative analysis often requires the use of a timed urine sample. The urinary microalbumin test measures the rate of albumin excretion in the urine using laboratory tests. This test is used to monitor kidney function of persons with **diabetes mellitus**. In diabetics, the excretion of greater than 200 μμg/mL albumin is predictive of impending **kidney disease**.

Precautions

Voided specimens

All patients should avoid intense athletic training or heavy physical work before the test, as these activities may cause small amounts of blood to appear in the urine. Many urinary constituents are labile, and samples should be tested within one hour of collection or refrigerated. Samples may be stored at 36–46°F (2–8°C) for up to 24 hours for chemical urinalysis tests; however, the microscopic examination should be performed within four hours of collection, if possible. To minimize sample contamination, women who require a urinalysis during menstruation should insert a fresh tampon before providing a urine sample.

Over two dozen drugs are known to interfere with various chemical urinalysis tests. These include:

- ascorbic acid
- chlorpromazine
- L-dopa
- nitrofurantoin (Macrodantin, Furadantin)
- penicillin
- phenazopyridine (Pyridium)
- rifampin (Rifadin)
- tolbutamide

The preservatives that are used to prevent loss of glucose and cells may affect biochemical test results. The use of preservatives should be avoided whenever possible in urine tests.

Description

Routine urinalysis consists of three testing groups: physical characteristics, biochemical tests, and microscopic evaluation.

Physical tests

The physical tests measure the color, transparency (clarity), and specific gravity of a urine sample. In some cases, the volume (daily output) may be measured. Color and transparency are determined from visual observation of the sample.

COLOR. Normal urine is straw yellow to amber in color. Abnormal colors include bright yellow, brown, black (gray), red, and green. These pigments may result from medications, dietary sources, or diseases. For example, red urine may be caused by blood or hemoglobin, beets, medications, and some porphyrias. Black-gray urine may result from melanin (**melanoma**) or homogentisic acid (alkaptonuria, a rare metabolic disorder). Bright yellow urine may be caused by bilirubin (a

KEY TERMS

Acidosis—A condition of the blood in which bicarbonate levels are below normal.

Alkalosis—A condition of the blood and other body fluids in which bicarbonate levels are higher than normal.

Bilirubin—A yellow bile pigment found as sodium (soluble) bilirubinate or as an insoluble calcium salt found in gallstones.

Biliverdin—A green bile pigment formed from the oxidation of heme, which is a bilin with a structure almost identical to that of bilirubin.

Cast—An insoluble gelled protein matrix that takes the form of the renal tubule in which it was deposited. Casts are washed out by normal urine flow.

Catheter—A thin flexible tube inserted through the urethra into the bladder to allow urine to flow out.

Clean-catch specimen—A urine specimen that is collected from the middle of the urine stream after the first part of the flow has been discarded.

Cystine—An amino acid normally reabsorbed by the kidney tubules. Cystinuria is an inherited disease in which cystine and some other amino acids are not reabsorbed by the body in normal amounts. Cystine crystals then form in the kidney, which leads to obstructive renal failure.

Epithelium—A general term for the layer of cells that lines blood vessels or small body cavities.

Ketones—Substances produced during the breakdown of fatty acids. They are produced in excessive amounts in diabetes and certain other abnormal conditions.

Meatus—A general term for an opening or passageway in the body. The urethral meatus should be cleansed before a urine sample is collected.

pH—A chemical symbol that denotes the acidity or alkalinity of a fluid, ranging from 1 (more acid) to 14 (more alkaline).

Porphyrias—A group of disorders involving heme biosynthesis, characterized by excessive excretion of porphyrins. The porphyrias may be either inherited or acquired (usually from the effects of certain chemical agents).

Trichomonads—Parasitic protozoa commonly found in the digestive and genital tracts of humans and other animals. Some species cause vaginal infections in women characterized by itching and a frothy discharge.

Turbidity—The degree of cloudiness of a urine sample (or other solution).

Urethra—The tube that carries urine from the bladder to the outside of the body.

Urinalysis (plural, urinalyses)—The diagnostic testing of a urine sample.

Voiding—The medical term for emptying the bladder or urinating.

bile pigment). Green urine may be caused by a bile pigment or certain medications. Orange urine may be caused by some medications or excessive urobilinogen (a chemical produced in the intestines). Brown urine may be caused by excessive amounts of porphobilin or urobilin (chemical relatives of urobilinogen).

TRANSPARENCY. Normal urine is transparent. Turbid (cloudy) urine may be caused by either normal or abnormal processes. Normal conditions giving rise to turbid urine include precipitation of crystals, mucus, or vaginal discharge. Abnormal causes of turbidity include the presence of blood cells, yeast, and bacteria.

SPECIFIC GRAVITY. The specific gravity of urine is a measure of the concentration of dissolved solutes (substances in a solution), and it reflects the ability of the kidneys to concentrate the urine (conserve water). Specific gravity is usually measured by determining the refractive index of a urine sample (refractometry) or by chemical analysis. Specific gravity varies with fluid and solute intake. It will be increased (above 1.035) in persons with diabetes mellitus and persons taking large amounts of medication. It will also be increased after radiologic studies of the kidney owing to the excretion of x-ray contrast dye. Consistently low specific gravity (1.003 or less) is seen in persons with **diabetes insipidus**. In renal (kidney) failure, the specific gravity remains equal to that of blood plasma (1.008–1.010) regardless of changes in the patient's salt and water intake. Urine volume below 400 mL per day is considered oliguria (low urine production) and may occur in persons who are dehydrated and those with some kidney diseases. A volume in excess of 2 liters (slightly more than 2 quarts) per day is considered polyuria (excessive urine production); it is common in persons with diabetes mellitus and diabetes insipidus.

Biochemical tests

Biochemical testing of urine is performed using dry reagent strips, often called dipsticks. A urine

WWW.BOOKBAZ.IR

dipstick consists of a white plastic strip with absorbent microfiber cellulose pads attached to it. Each pad contains the dried reagents needed for a specific test. The person performing the test dips the strip into the urine, lets it sit for a specified amount of time, and compares the color change to a standard chart.

Additional tests are available for measuring the levels of bilirubin, protein, glucose, ketones, and urobilinogen in urine. In general, these individual tests provide greater sensitivity and permit detection of a lower concentration of the respective substance.

PH. A combination of pH indicators (methyl red and bromothymol blue) react with hydrogen ions (H^+) to produce a color change over a pH range of 5.0 to 8.5. The pH measurements are useful in determining metabolic or respiratory disturbances in acid-base balance. For example, kidney disease often results in retention of H^+ (reduced acid excretion). The pH varies with a person's diet, tending to be acidic in people who eat meat but more alkaline in vegetarians. The pH testing is also useful for the classification of urine crystals.

PROTEIN. Based upon a phenomenon called the "protein error of indicators," this test uses a pH indicator, such as tetrabromophenol blue, that changes color (at constant pH) when albumin is present in the urine. Albumin is important in determining the presence of glomerular damage. The glomerulus is the network of capillaries in the kidneys that filters low molecular weight solutes such as urea, glucose, and salts, but normally prevents passage of protein or cells from blood into filtrate. Albuminuria occurs when the glomerular membrane is damaged, a condition called **glomerulonephritis**.

GLUCOSE (SUGAR). The glucose test is used to monitor persons with diabetes. When blood glucose levels rise above 160 mg/dL, the glucose will be detected in urine. Consequently, glycosuria (glucose in the urine) may be the first indicator that diabetes or another hyperglycemic condition is present. The glucose test may be used to screen newborns for galactosuria and other disorders of carbohydrate metabolism that cause urinary excretion of a sugar other than glucose.

KETONES. Ketones are compounds resulting from the breakdown of fatty acids in the body. These ketones are produced in excess in disorders of carbohydrate metabolism, especially Type 1 diabetes mellitus. In diabetes, excess ketoacids in the blood may cause life-threatening acidosis and **coma**. These ketoacids and their salts spill into the urine, causing ketonuria. Ketones are also found in the urine in several other conditions, including **fever**; **pregnancy**; **glycogen storage diseases**; and weight loss produced by a carbohydrate-restricted diet.

BLOOD. Red cells and hemoglobin may enter the urine from the kidney or lower urinary tract. Testing for blood in the urine detects abnormal levels of either red cells or hemoglobin, which may be caused by excessive red cell destruction, glomerular disease, kidney or **urinary tract infection**, malignancy, or urinary tract injury.

BILIRUBIN. Bilirubin is a breakdown product of hemoglobin. Most of the bilirubin produced in humans is conjugated by the liver and excreted into the bile, but a very small amount of conjugated bilirubin is reabsorbed and reaches the general circulation to be excreted in the urine. The normal level of urinary bilirubin is below the detection limit of the test. Bilirubin in the urine is derived from the liver, and a positive test indicates hepatic disease or hepatobiliary obstruction.

SPECIFIC GRAVITY. Specific gravity is a measure of the ability of the kidneys to concentrate urine by conserving water.

NITRITE. Some disease bacteria, including the lactose-positive *Enterobacteriaceae*, *Staphylococcus*, *Proteus*, *Salmonella*, and *Pseudomonas*, are able to reduce nitrate in urine to nitrite. A positive test for nitrite indicates bacteriuria, or the presence of bacteria in the urine.

UROBILINOGEN. Urobilinogen is a substance formed in the gastrointestinal tract by the bacterial reduction of conjugated bilirubin. Increased urinary urobilinogen occurs in prehepatic **jaundice** (**hemolytic anemia**), hepatitis, and other forms of hepatic necrosis that impair the circulation of blood in the liver and surrounding organs. The urobilinogen test is helpful in differentiating these conditions from obstructive jaundice, which results in decreased production of urobilinogen.

LEUKOCYTES. The presence of white blood cells in the urine usually signifies a urinary tract infection, such as **cystitis**, or renal disease, such as **pyelonephritis** or glomerulonephritis.

Microscopic examination

A urine sample may contain cells that originated in the blood, the kidney, or the lower urinary tract. Microscopic examination of urinary sediment can provide valuable clues regarding many diseases and disorders involving these systems.

The presence of bacteria or yeast and white blood cells helps to distinguish between a urinary tract infection and a contaminated urine sample. White blood cells are not seen if the sample has been contaminated. The presence of cellular casts (casts containing RBCs, WBCs, or epithelial cells) identifies the kidneys, rather than the lower urinary tract, as the source of such cells.

Cellular casts and renal epithelial (kidney lining) cells are signs of kidney disease.

The microscopic examination also identifies both normal and abnormal crystals in the sediment. Abnormal crystals are those formed as a result of an abnormal metabolic process and are always clinically significant. Normal crystals are formed from normal metabolic processes; however, they may lead to the formation of renal calculi, or **kidney stones**.

Preparation

A urine sample is collected in an unused disposable plastic cup with a tight-fitting lid. A randomly voided sample is suitable for routine urinalysis, although the urine that is first voided in the morning is preferable because it is the most concentrated. The best sample for analysis is collected in a sterile container after the external genitalia have been cleansed using the midstream void (clean-catch) method. This sample may be cultured if the laboratory findings indicate bacteriuria.

Specific methods for collecting a clean-catch sample vary based on the patient:

- Females should use a clean cotton ball moistened with lukewarm water (or antiseptic wipes provided with collection kits) to cleanse the external genital area before collecting a urine sample. To prevent contamination with menstrual blood, vaginal discharge, or germs from the external genitalia, they should release some urine before beginning to collect the sample.
- Males should use a piece of clean cotton moistened with lukewarm water or antiseptic wipes to cleanse the head of the penis and the urethral meatus (opening). Uncircumcised males should draw back the foreskin. After the area has been thoroughly cleansed, they should use the midstream void method to collect the sample.
- For infants, a parent or healthcare worker should cleanse the baby's outer genitalia and surrounding skin. A sterile collection bag should be attached to the child's genital area and left in place until he or she has urinated. It is important not to touch the inside of the bag and to remove it as soon as a specimen has been obtained.

Urine samples can also be obtained via bladder catheterization, a procedure used to collect uncontaminated urine when the patient cannot void. A catheter is a thin flexible tube that a healthcare professional inserts through the urethra into the bladder to allow urine to flow out. To minimize the risk of infecting the patient's bladder with bacteria, many clinicians use a Robinson catheter, which is a plain rubber or latex tube that is removed as soon as the specimen is collected. If urine for culture is to be collected from an indwelling catheter, it should be aspirated (removed by suction) from the line using a syringe and not removed from the bag in order to avoid contamination.

Suprapubic bladder aspiration is a collection technique sometimes used to obtain urine from infants younger than six months or urine directly from the bladder for culture. The doctor withdraws urine from the bladder into a syringe through a needle inserted through the skin.

Aftercare

The patient may return to normal activities after collecting the sample and may start taking any medications that were discontinued before the test.

Risks

There are no risks associated with voided specimens. The risk of bladder infection from catheterization with a Robinson catheter is about 3%.

Results

Normal urine is a clear straw-colored liquid but may also be slightly hazy. It has a slight odor, and some laboratories will note strong or atypical odors on the urinalysis report. A normal urine specimen may contain some normal crystals as well as squamous or transitional epithelial cells from the bladder, lower urinary tract, or vagina. Urine may contain transparent (hyaline) casts, especially if it was collected after vigorous **exercise**. The presence of hyaline casts may be a sign of kidney disease, however, when the cause cannot be attributed to exercise, running, or medications. Normal urine contains a small amount of urobilinogen, and may contain a few RBCs and WBCs. Normal urine does *not* contain detectable amounts of glucose or other sugars, protein, ketones, bilirubin, bacteria, yeast cells, or trichomonads. Normal values used in many laboratories are given below:

- Glucose: negative (quantitative less than 130 mg/day or 30 mg/dL)
- Bilirubin: negative (quantitative less than 0.02 mg/dL)
- Ketones: negative (quantitative 0.5–3.0 mg/dL)
- pH: 5.0–8.0
- Protein: negative (quantitative 15–150 mg/day, less than 10 mg/dL)
- Blood: negative
- Nitrite: negative

WWW.BOOKBAZ.IR

- Specific gravity: 1.015–1.025
- Urobilinogen: 0–2 Ehrlich units (quantitative 0.3–1.0 Ehrlich units)
- Leukocyte esterase: negative
- Red blood cells: 0–2 per high power field
- White blood cells: 0–5 per high power field (0–10 per high power field for some standardized systems)

Urinary anti-infectives

Definition

Urinary anti-infectives are medicines used to treat or prevent urinary tract infections. The urinary tract is the passage through which urine flows from the kidneys and bladder to exit the body.

Purpose

Normally, no bacteria or other disease-causing organisms live in the bladder. Likewise, the urethra—the tube-like structure that carries urine from the bladder out of the body—usually has either no bacteria or not enough to cause problems. The bladder, urethra, and other parts of the urinary tract may become infected, however, when disease-causing organisms invade from other body regions or from outside the body. Urinary anti-infectives are used to treat these infections or to prevent them in people who get them often.

Although many **antibiotics** and some **sulfonamides** are equally effective in treating urinary tract infections, urinary anti-infectives have the advantage of being active only in the urinary tract. This means they are less likely to cause development of resistant microorganisms, or to cause **diarrhea** by destroying the bacteria in the large intestine.

Some urinary anti-infectives have been used to prevent urinary tract infections, but the evidence that they are effective for this purpose is limited.

Description

Commonly used urinary anti-infectives include methenamine (Urex, Hiprex, Mandelamine), ciprofloxacin (Cipro), nitrofurantoin (Macrobid, Furatoin, and other brands), and levofloxacin (Levaquin). These medicines are available only with a physician's prescription and come in capsule, tablet, granule, and liquid forms.

Ciprofloxacin and levofloxacin are quinolones, synthetic substances that fight bacteria. The first quinolone to be approved for clinical use, nalidixic acid, has been used to treat urinary tract infections since 1967. As a result, there is high antibacterial resistance to the medication, particularly for *Escherichia coli* (*E. coli*), a type of Enterobacteriaceae that is found in the digestive tract and is among the most common causes of urinary tract infections.

Urinary anti-infectives are available only with a physician's prescription. They come in capsule, tablet, granular, and liquid forms.

Recommended dosage

Methenamine

For adults and children 12 years and over, the usual dosage is 1 gram, taken either twice a day or four times a day, depending on the form of the medication that the doctor prescribes. For children aged 6 to 12, the dosage ranges from 500 mg taken two to four times a day to 1 gram taken twice a day, again depending on the form of the drug. A physician must determine the dose for children under six years.

Urinary anti-infectives will not work properly unless the urine is acidic, with a pH reading of 5.5 or lower. The physician who prescribes the medicine will

explain how to test the urine's acidity. The doctor may suggest dietary changes that will make the urine more acidic, such as eating more protein; drinking cranberry juice; eating plums and prunes while avoiding most other fruits; and cutting down on milk and other dairy products. The patient should also avoid taking **antacids**.

Ciprofloxacin

The recommended adult dose for an uncomplicated **urinary tract infection** is 250 mg of immediate-release ciprofloxacin every 12 hours for three days. The extended-release pills can be taken in 500 mg doses every 24 hours for three days. Children usually are not given ciprofloxacin as a first choice, but when they are, they receive about 10 to 20 mg every 12 hours for 10 or more days, depending on their weight and severity of the infection. Ciprofloxacin also can be administered intravenously.

Nitrofurantoin

The usual dose for adults and adolescents is 50–100 mg every six hours. For extended-release tablets, the usual dosage is 100 mg every 12 hours for seven days.

A physician must determine the correct dose of all forms of nitrofurantoin for children one month and older according to the child's body weight. Children under one month should not take this medicine.

Levofloxacin

Adults with complicated urinary tract infections generally receive 250 mg or levofloxacin a day for 10 days or receive the medication intravenously.

Precautions

Although generally safe, anti-infectives have some side effects. It always is best to inquire about the medication's effects and interactions. In addition, overuse of antibiotics to treat infections could lead to drug-resistant infections. Because of this, doctors only prescribe urinary anti-infectives when necessary.

Methenamine

People with certain medical conditions may have additional problems with this medicine; it may worsen liver or **kidney disease**.

Ciprofloxacin

Ciprofloxacin can worsen muscle weakness in people who have a nervous system disorder called **myasthenia gravis** and increase risk of **tendinitis**. The medication also makes the skin more sensitive to sunlight or other ultraviolet light.

Nitrofurantoin

Pregnant women should not take this medicine within two weeks of their delivery date and should not use it during labor and delivery, as this could cause problems in the baby.

Women who are breast-feeding should check with their physicians before using this medicine, as it passes into breast milk and could cause problems. This is especially true for babies with glucose-6-phosphate dehydrogenase (G6PD) deficiency. The medicine also should not be given directly to babies up to one month of age, as they are particularly sensitive to its effects.

Older people may be more likely to experience side effects when taking nitrofurantoin, because they are more sensitive to the drug's effects.

Taking nitrofurantoin may also cause problems for people with certain medical conditions. Side effects may be greater, for example, in people with lung disease or nerve damage. In people with kidney disease, the medicine may not work as well as it should and may cause more side effects. Those with glucose-6-phosphate dehydrogenase (G6PD) deficiency who take nitrofurantoin may develop anemia.

People with diabetes should be aware that this medicine may cause false results on some urine sugar tests. They should check with a physician before making any changes in diet or diabetes medicine based on the results of a urine test.

Levofloxacin

Levofloxacin is a quinolone antibiotic, so people who are allergic to quinolone antibiotics may experience a reaction. The medication can affect the heart's rhythm and cause serious problems by making a person's heart beat irregularly or too rapidly. Levofloxacin also can cause muscle weakness or tendinitis.

Symptoms should improve within a few days of starting to take a urinary anti-infective. If they do not, or if they become worse, check with a physician. Patients who need to take this medicine for long periods should see their physicians regularly, so that the physician can check their progress.

Individuals who have had unusual reactions to urinary anti-infectives in the past should let their physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances. Patients taking nalidixic acid should tell their physicians if they have ever

WWW.BOOKBAZ.IR

had reactions to medicines such as cinoxacin (Cinobac), ciprofloxacin (Cipro), enoxacin (Penetrex), norfloxacin (Noroxin), or ofloxacin (Floxin), all of which are also used to treat or prevent infections. Anyone taking nitrofurantoin should let the physician know if he or she has had an unusual reaction to medicines such as furazolidone (Furoxone) or nitrofurazone (Furacin).

Side effects

While each drug is associated with known side effects, individuals who have unusual symptoms while taking a urinary anti-infective should contact their physician.

Methenamine

Nausea and vomiting are not common but may occur. These side effects do not need medical attention unless they are severe. Taking oral methenamine with food or milk can ease some of the nausea. One side effect that should be brought to a physician's attention immediately is a skin rash.

Ciprofloxacin

Taking ciprofloxacin can cause a patient to have nausea, **vomiting**, stomach **pain**, and diarrhea. **Heartburn** also can be a side effect, but people on ciprofloxacin should not take certain antacids immediately before taking the medication. **Headache** also has been reported. More serious side effects might indicate a serious reaction and should be reported immediately to a doctor. These include difficulty breathing or swallowing, **hives**, **rashes**, tingling or swelling of the face, and **wheezing**.

Nitrofurantoin

This medicine may make the urine turn reddish-yellow to brown, but it is nothing to worry about. Other possible side effects that do not need medical attention unless they become severe include pain in the stomach or abdomen, stomach upset, diarrhea, loss of appetite, and nausea or vomiting.

Anyone who has chest pain, breathing problems, **fever**, chills, or a **cough** while taking nitrofurantoin should consult their physician immediately.

Levofloxacin

Some side effects are minor, such as nausea, vomiting, stomach pain, **constipation**, and diarrhea. If diarrhea becomes severe, the person taking levofloxacin should notify the prescribing doctor. Other serious side effects include skin rashes, **itching**, **fainting**, rapid or irregular heartbeat, and unusual bruising or bleeding. Severe allergic reactions are rare but can occur; symptoms include a rash, itching, swelling around the mouth and throat, and **dizziness**.

KEY TERMS

Anticoagulant—A type of medication given to prevent the formation of blood clots. Anticoagulants are sometimes called blood thinners.

Bacteria—Microscopically small one-celled forms of life that cause many diseases and infections.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency—An inherited disorder in which the body lacks an enzyme that normally protects red blood cells from toxic chemicals. Certain drugs can cause patients' red blood cells to break down, resulting in anemia. This may also happen when they have a fever or an infection. The condition usually occurs in males. About 10% of black males have it, as do a small percentage of people from the Mediterranean region.

Granule—A small grain or pellet. Medicines that come in granule form are usually mixed with liquids or sprinkled on food before they are taken.

pH—A measure of the acidity or alkalinity of a substance or compound. The pH scale ranges from 0 to 14. Values below 7 are acidic; values above 7 are alkaline.

Quinolones—A group of synthetic antibacterial drugs originally derived from quinine. Nalidixic acid is the first quinolone that was approved for clinical use.

Interactions

Patients should check with a physician or pharmacist before combining a urinary anti-infective with any other prescription or nonprescription (over-the-counter) medicine. Patients who are taking any kind of herbal preparation or other alternative medicine should give their doctor and pharmacist a list of all the compounds that they use on a regular basis. Most of these preparations are unlikely to interact with urinary anti-infectives, but there is much that is still unknown about possible interactions between standard prescription medications and alternative medicines.

Methenamine

Certain medicines may make methenamine less effective. These include thiazide **diuretics** (water pills) and medicines that make the urine less acidic, such as antacids, bicarbonate of soda, and the drugs acetazolamide

(Diamox), dichlorphenamide (Daranide), and methazolamide (Neptazane), which are used to treat **glaucoma**, **epilepsy**, **altitude sickness**, and other conditions.

Ciprofloxacin

Several medications can interact with ciprofloxacin. Among them are tizanidine (Zanaflex) and warfarin (Coumadin, Jantoven). Several antidepressants and antipsychotic medicines can also cause an interaction, as can high levels of **caffeine**.

Nitrofurantoin

Patients should inform their physicians of any medications or herbal supplements they are taking before using nitrofurantoin. Antacids, antibiotics, and benztropine (Cogentin) are some of the medications or supplements that may cause reactions.

Levofloxacin

Several medications can interact with levofloxacin, including tizanidine (Zanaflex), warfarin (Coumadin, Jantoven), and **nonsteroidal anti-inflammatory drugs**. Several antidepressants and antipsychotic medicines can also cause interactions.

Urinary catheterization

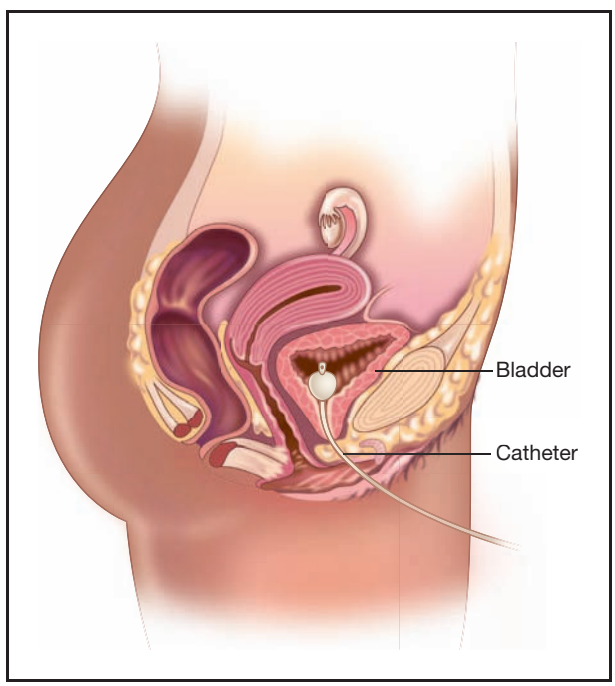
Definition

Urinary catheterization is the insertion of a catheter through the urethra into the urinary bladder for withdrawal of urine. Straight catheters are used for intermittent drainage, while indwelling (Foley) catheters are inserted and retained in the bladder for continuous drainage of urine into a closed system.

Purpose

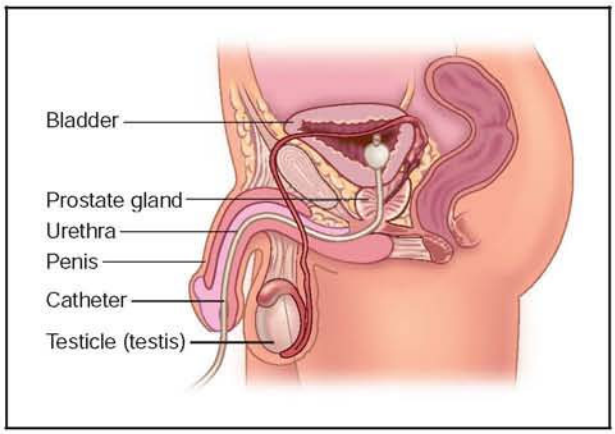
Intermittent catheterization is used to:

- obtain a sterile urine specimen for diagnostic evaluation



Female urinary catheterization. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

WWW.BOOKBAZ.IR



Male urinary catheterization. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

- empty bladder contents when an individual is unable to void (urinate) due to urinary retention, bladder distention, or obstruction
- measure residual urine after urinating
- instill medication for a localized therapeutic effect in the bladder
- instill contrast material (dye) into the bladder for cystourethrography (x-ray study of the bladder and urethra)
- empty the bladder for increased space in the pelvic cavity to protect the bladder during labor and delivery or during pelvic and abdominal surgery
- monitor the urinary output and fluid balance of critically ill patients

Indwelling catheterization is used to:

- provide palliative care for incontinent persons who are terminally ill or severely impaired and for whom bed and clothing changes are uncomfortable
- manage skin ulcerations caused or exacerbated by incontinence
- maintain a continuous outflow of urine for persons undergoing surgical procedures that cause a delay in bladder sensation, or for individuals with chronic neurological disorders that cause paralysis or loss of sensation in the perineal area
- keep with standard preoperative preparation for urologic surgery and procedures for bladder outlet obstruction
- provide relief for persons with an initial episode of acute urinary retention, allowing the bladder to regain its normal muscle tone

Description

Urinary catheterization can be performed by healthcare practitioners, by home caregivers, or by patients themselves in hospitals, long-term care facilities, or personal homes.

The male urethral orifice (urinary meatus) is a vertical, slit-like opening, 0.15–0.2 in. (4–5 mm) long, located at the tip of the penis. The foreskin of the penis may conceal the opening. This must be retracted to be able to insert a catheter.

The female urethral orifice is a vertical, slit-like, or irregularly ovoid (egg-shaped) opening, 0.16–0.2 in. (4–5 mm) in diameter, located between the clitoris and the vagina. The urinary meatus (opening) is concealed between the labia minora, which are the small folds of tissue that need to be separated to view the opening and insert a catheter. Perineal care or cleansing may be required to ensure a clean procedural environment.

The male urethra is longer than the female urethra and has two curves in it as it passes through the penis to the bladder. Catheterization of the male patient is traditionally performed without the use of local anesthetic gel to facilitate catheter insertion. Glands along the urethra provide some natural lubrication. Older men may require lubrication; in such an instance, an anesthetic or antibacterial lubricant should be used.

Since there are no lubricating glands in the female urethra, the risk of **trauma** from a simple catheter insertion is increased. Therefore, an ample supply of an anesthetic or antibacterial lubricant should be used.

When inserting a urinary catheter, the healthcare provider will first wash the hands and put on gloves and clean the skin of the area around the urethra (in females) or the tip of the penis (in males). The catheter is threaded up the urethra and into the bladder until the urine starts to flow. Once the catheter is inserted, it is secured as appropriate for the catheter type. A straight catheter is typically secured with adhesive tape. An indwelling catheter is secured by inflating a bulb-like device inside of the bladder.

Catheter choices

TYPES. Silastic catheters have been recommended for short-term catheterization after surgery because they are known to decrease incidence of **urethritis** (inflammation of the urethra). However, due to lower cost and acceptable outcomes, latex is the catheter of choice for long-term catheterization. Silastic catheters should be reserved for individuals who are allergic to latex products.

Additional types of catheters include:

- PTFE (plastic)-coated latex indwelling (Foley) catheters
- hydrogel-coated latex indwelling catheters
- pure silicone indwelling catheters
- silicone-coated latex indwelling catheters

SIZE. The diameter of a catheter is measured in millimeters. Authorities recommend using the narrowest and softest tube that will serve the purpose of the catheterization. Rarely is a catheter larger than size 18 F(rench) required, and sizes 14 or 16 F are used more often. Catheters greater than size 16 F have been associated with patient discomfort and urine bypassing. A size 12 F catheter has been successfully used in children and in patients with urinary restriction.

DRAINAGE SYSTEM. The healthcare provider should discuss the design, capacity, and emptying mechanism of several urine drainage bags with the patient. For patients with normal bladder sensation, a catheter valve for intermittent drainage may be an acceptable option.

Preparation

Healthcare practitioners performing the catheterization should have a good understanding of the anatomy and **physiology** of the urinary system, be trained in antiseptic techniques, and have proficiency in catheter insertion and catheter care.

After determining the primary purpose for the catheterization, practitioners should give the patient and primary caregiver a detailed explanation. Patients requiring self-catheterization should be instructed and trained in the technique by a qualified health professional.

Sterile disposable catheterization sets are available in clinical settings and for home use. These sets contain most of the items needed for the procedure, such as antiseptic agent, perineal drapes, gloves, lubricant, specimen container, label, and tape. Anesthetic or antibacterial lubricant, catheter, and a drainage system may need to be added.

Aftercare

Patients using intermittent catheterization to manage incontinence may require a period of adjustment as they try to establish a catheterization schedule that is adequate for their normal fluid intake.

Antibiotics should not be prescribed as a preventative measure for patients at risk for **urinary tract infection** (UTI). Prophylactic use of antibacterial agents may lead to the development of drug-resistant bacteria. Patients who practice intermittent self-catheterization can reduce their risk for UTI by using antiseptic techniques for insertion and catheter care.

The extended portion of the catheter should be washed with a mild soap and warm water to keep it free of accumulated debris.

If the patient is sexually active, the practitioner must explain that intercourse can take place with the catheter in place. The patient and the patient's partner can also be taught to remove the catheter before intercourse and replace it with a new one afterwards.

Risks

Complications that may occur from the catheterization procedure include:

- trauma or introduction of bacteria into the urinary system, leading to infection and, rarely, septicemia
- trauma to the urethra or bladder from incorrect insertion or attempting to remove the catheter with the balloon inflated; repeated trauma may cause scarring or stricture (narrowing) of the urethra
- passage of urine around the catheter; inserting a different size catheter can minimize this problem

Urinary catheterization should be avoided whenever possible. Clean intermittent catheterization, when practical, is preferable to long-term catheterization.

Catheters should not be routinely changed. Before the catheter is changed, each patient should be monitored for indication of obstruction, infection, or complications. Some patients require weekly catheter changes, while others may need one change in several weeks. Fewer catheter changes will reduce trauma to the urethra and reduce the incidence of UTI.

Because the urinary tract is normally a sterile system, catheterization presents the risk of causing a UTI. The presence of residual urine in the bladder due to incomplete voiding provides an ideal environment for bacterial growth. The catheterization procedure must be sterile, and the catheter must be free from bacteria.

Frequent intermittent catheterization and long-term use of indwelling catheterization predisposes a person to UTI. Care should be taken to avoid trauma to the urinary meatus or urothelium (urinary lining) with catheters that are too large or inserted with insufficient use of lubricant. Patients with an indwelling catheter must be reassessed periodically to determine if an alternative treatment will be more effective.

Males

Phimosis is constriction of the prepuce (foreskin) so that it cannot be drawn back over the glans penis.

WWW.BOOKBAZ.IR

KEY TERMS

Catheter—A tube for evacuating or injecting fluid.

Foley catheter—A double-channel retention catheter; one channel provides for the inflow and outflow of bladder fluid, the second (smaller) channel is used to fill a balloon that holds the catheter in the bladder.

Incontinence—The inability to retain urine or control urine flow.

Intermittent catheterization—Periodic catheterization to facilitate urine flow.

Perineal area—The genital area between the vulva and anus in a woman and between the scrotum and the anus in a man.

Prophylactic—Intended to prevent or protect against disease.

Septicemia—An infection in the blood.

Urethra—The tube that allows passage of urine out of the urinary bladder.

Urethritis—Inflammation of the urinary bladder.

Urinary retention—The inability to void (urinate) or discharge urine.

This may make it difficult to identify the external urethral meatus. Care should be taken when catheterizing men with phimosis to avoid trauma from forced retraction of the prepuce or by incorrect positioning of the catheter.

Females

Sexual activity and **menopause** can also compromise the sterility of the urinary tract. Irritation of the urethra during intercourse promotes the migration of perineal bacteria into the urethra and bladder, causing UTIs. Postmenopausal women may experience more UTIs than younger women.

Results

A catheterization program that includes correctly inserted catheters and is appropriately maintained will usually control **urinary incontinence**.

The patient and the patient's caregiver should be taught to use aseptic technique for catheter care. Nursing interventions and patient education can make a difference in the incidence of UTIs in hospitals, nursing homes, and **home care** settings.

Morbidity and mortality rates

Injuries resulting from catheterization are infrequent. Deaths are extremely rare. Both complications are usually due to infections that result from improper catheter care.

Alternatives

An alternative to catheterization is to use a pad to absorb voided urine.

Urinary diversion surgery

Definition

A urinary diversion involves removal of the urinary bladder and adjacent tissues and organs and rerouting of the urinary stream. This may involve creation of an artificial opening in the abdomen called an **ostomy**.

Purpose

A urinary diversion is created as a means to treat cancer of the bladder, when conservative measures have been unsuccessful, or when there is recurrence of the disease invading the muscle wall. Congenital deformities or traumatic injury may also necessitate formation of a urinary diversion.

Description

Under general **anesthesia**, an incision is made in the abdomen. The ureters (tubes that carry urine away from the kidneys) are cut and tied. The bladder and surrounding tissues are cut free and removed. The ureters are then attached to a portion of the intestine. The most common types of urinary diversion are:

- Ileal conduit. Ureters are attached to a portion of the small intestine, the ileum, one end of which is brought through the abdominal wall as a conduit for the urine, creating a stoma
- Ureterosigmoidostomy. The ureters are attached to a portion of the large intestine, the sigmoid, which allows the urine to flow through the large intestine and out through the rectum
- Cutaneous ureterostomy. Bringing the detached ureters through the abdominal wall and attaching it to an opening in the skin

Following creation of an artificial opening to drain the urine, ureteral stents (tubes that go through the stoma and up into the ureters) are often inserted and left in place to allow urine to drain freely from the kidneys, without risk of blockage from swelling due to surgery. The muscles are replaced and sewn together. A transparent pouch is applied to the abdomen to collect urine and attached to a bedside drainage bag. The incision is closed with sutures or clips ("staples"), which are usually removed about a week after surgery.

An alternative to a conventional urinary diversion is the continent urinary diversion. In this surgical procedure, a "false bladder" is constructed within the abdomen, using several lengths of small or large intestine. The ureters are sewn to this new reservoir for urine and nipple valves which are created at two sites: the abdominal wall for continence, and where the ureters are implanted, to prevent reflux of urine back to the kidneys. The patient is then taught to catheterize the reservoir to drain urine at regular intervals during the day. Although a continent diversion is not suitable for every patient who requires urinary diversion, it is an option to be considered.

Preparation

As with any surgical procedure, the patient will be required to sign a consent form after the procedure is explained thoroughly. Blood and urine studies, along with various x rays and an electrocardiogram (EKG), may be ordered as the doctor deems necessary. If creation of an ostomy is planned, the patient should visit an enterostomal therapist, who will mark an appropriate place on the abdomen for a stoma and offer preoperative education on ostomy management.

Eating or drinking is prohibited after midnight the night before the surgery. Oral anti-infectives, such as neomycin, erythromycin, or kanamycin sulfate, may be ordered to decrease bacteria in the intestine and help prevent postoperative infection. A **nasogastric tube** is inserted the day of surgery, or during surgery, to remove gastric secretions and prevent **nausea and vomiting**.

Aftercare

Postoperative care for a patient with a urinary diversion, as with those who have had any major surgery, involves monitoring of blood pressure, pulse, respirations, and temperature. Breathing tends to be shallow because of the effect of anesthesia, and the patient is reluctant to breathe deeply and experience **pain** that is caused by the abdominal incision. The patient is shown how to support the operative site during deep breathing and coughing and is given pain medication as necessary. Fluid intake and output are measured, and the operative site is observed for color and amount of wound drainage. The nasogastric tube will remain in place, attached to low intermittent suction, until bowel activity resumes. Fluids and electrolytes are infused intravenously until the patient's diet can gradually be resumed, beginning with liquids. The patient is usually able to move about in 8–24 hours after surgery and is discharged from the hospital in 5–10 days.

If an ostomy has been placed, the patient and close family members will be educated on how to care for it. Determination of appropriate pouching supplies and a schedule of how often to change the pouch should be established. Regular assessment and meticulous care of the skin surrounding the stoma is important to maintain an adequate surface on which to apply the pouch.

WWW.BOOKBAZ.IR

KEY TERMS

Ischemia—A compromise in blood supply to body tissues that causes tissue damage or death.

Ostomy—A surgically created opening in the abdomen for elimination of waste products (urine or stool).

The pouch should be connected to a bedside drainage bag at night to prevent large volumes of urine from collecting in the pouch. Otherwise, the weight of the pouch could cause disruption of the pouch seal and leakage of urine onto the surrounding skin. Often, an enterostomal therapist will visit the patient at home after discharge to help the new ostomy patient make the transition back to normal daily activities.

Risks

Potential complications of urinary diversion surgery include:

- excessive bleeding
- surgical wound infection
- thrombophlebitis (inflammation and blood clot to veins in the legs)
- pneumonia
- pulmonary embolism (blood clot or air bubble in the lungs' blood supply)

Results

Complete healing is expected without complications. The amount of time required for recovery from the surgery may vary depending of the patient's overall health status prior to surgery. The patient with a urinary diversion, without other medical complications, should be able to resume all daily activities once recovered from the surgery.

Abnormal results

The doctor should be made aware of any of the following problems after surgery:

- increased pain, swelling, redness, drainage, or bleeding in the surgical area
- headache, muscle aches, dizziness, or fever
- increased abdominal pain or swelling, constipation, nausea, or vomiting

Stomal complications to be monitored include:

- Stomal tissue death (necrosis). This occurs because of inadequate blood supply, which is usually visible 12 to 24 hours after surgery and may require additional surgery
- Stoma flush or below the abdomen surface (retraction). Caused by insufficient stomal length, this may be managed by use of special pouching supplies. Elective revision of the stoma is also an option
- Narrowing at the opening of the stoma (stenosis). Often associated with infection around the stoma or scarring, mild stenosis can be removed under local anesthesia. Severe stenosis may require surgery for stomal revision
- Parastomal hernia. The bowel causes a bulge in the abdominal wall next to the stoma. This is usually due to placement of the stoma where the abdominal wall is weak or an overly large opening in the abdominal wall. Use of an ostomy support belt and special pouching supplies may be adequate. If severe, the defect in the abdominal wall should be repaired and the stoma moved to another location

Urinary incontinence

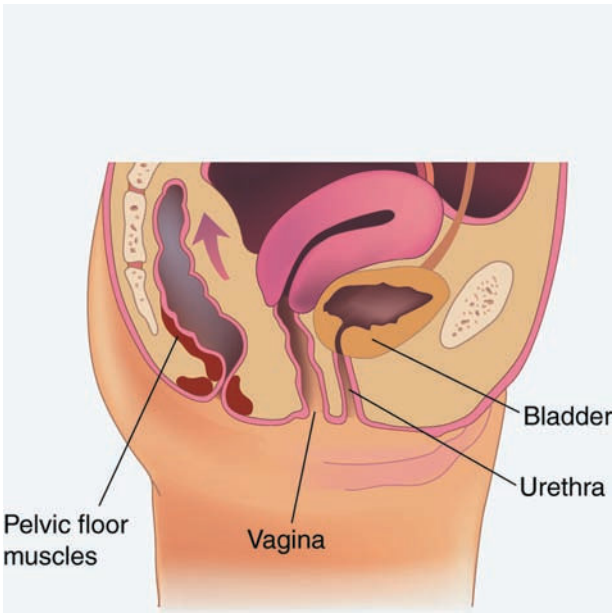
Definition

Urinary incontinence is unintentional loss of urine that is sufficient enough in frequency and amount to cause physical and/or emotional distress in the person experiencing it.

Description

Approximately 13 million Americans suffer from urinary incontinence. Women are affected by the disorder more frequently than men; one in 10 women under age 65 suffers from urinary incontinence. A study published in late 2002 found that between 21% and 29% of adult women in the workforce reported at least one episode of urinary incontinence each month. Older Americans, too, are more prone to the condition. Twenty percent of Americans over age 65 are incontinent. In general, the condition is underrecognized and undertreated.

There are five major categories of urinary incontinence: overflow, **stress**, urge, functional, and reflex.



Strengthening the pelvic floor muscles by performing Kegel exercises helps to alleviate stress incontinence in women. Contract the pelvic floor muscles as if stopping an imaginary flow of urine. Hold for 10 seconds and repeat. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

- Overflow incontinence. Overflow incontinence is caused by bladder dysfunction. Individuals with this type of incontinence have an obstruction to the bladder or urethra, or a bladder that does not contract properly. As a result, their bladders do not empty completely, and they have problems with frequent urine leakage.
- Stress incontinence. Stress incontinence occurs when an individual involuntarily loses urine after pressure is placed on the abdomen (i.e., during exercise, sexual activity, sneezing, coughing, laughing, or hugging).
- Urge incontinence. Urge incontinence occurs when an individual feels a sudden need to urinate, and cannot control the urge to do so. As a consequence, urine is involuntarily lost before the individual can get to the toilet.
- Functional incontinence. Individuals who have control over their own urination and have a fully functioning urinary tract, but cannot make it to the bathroom in time due to a physical or cognitive disability, are functionally incontinent. These individuals may suffer from arthritis, Parkinson's disease, multiple sclerosis, or Alzheimer's disease.
- Reflex incontinence. Individuals with reflex incontinence lose control of their bladder without warning. They typically suffer from neurological impairment.

In some cases, an individual may develop short-term or *acute incontinence*. Acute incontinence may occur as a symptom or by-product of illness, as a side effect of medication, or as a result of dietary intake. The condition is typically easily resolved once the cause is determined and addressed.

Causes and symptoms

Urinary incontinence can be caused by a wide variety of physical conditions, including:

- Childbirth. Childbirth can weaken the pelvic muscles and cause the bladder to lose some support from surrounding muscles, resulting in stress incontinence.
- Dysfunction of the bladder and/or the urinary sphincter. In a continent individual, as the bladder contracts, the outlet that releases urine into the urethra (bladder sphincter) opens and urine exits the body. In individuals with overflow incontinence, bladder contractions and dilation of the sphincter do not occur at the same time.
- Enlarged prostate. In men, an enlarged prostate gland can obstruct the bladder, causing overflow incontinence.
- Hysterectomy or other gynecological surgery. Any surgery involving the urogenital tract runs the risk of damaging or weakening the pelvic muscles and causing incontinence.
- Menopause. The absence of estrogen in the postmenopausal woman can cause the bladder to drop, or prolapse.
- Neurological conditions. The nervous system sends signals to the bladder telling it when to start and stop emptying. When the nervous system is impaired, incontinence may result. Neurological conditions such as multiple sclerosis, stroke, spinal cord injuries, or a brain tumor may cause the bladder to contract involuntarily, expelling urine without warning or to cease contractions completely, causing urinary retention.
- Obesity. Individuals who are overweight have undue pressure placed on their bladder and surrounding muscles.
- Obstruction. A blockage at the bladder outlet may permit only small amounts of urine to pass, resulting in urine retention and subsequent overflow incontinence. Tumors, calculi, and scar tissue can all block the flow of urine. A urethral stricture, or narrow urethra caused by scarring or inflammation, may also result in urine retention.

Acute incontinence is a temporary condition caused by a number of factors, including:

- Bladder irritants. Substances in the urine that irritate the bladder may cause the bladder muscle to malfunction.

WWW.BOOKBAZ.IR

The presence of a urinary tract infection and the ingestion of excess caffeine can act as irritants. Highly concentrated urine resulting from low fluid intake may also irritate the bladder.

- Constipation. Constipation can cause incontinence in some individuals. Stool that is not passed presses against the bladder and urethra, triggering urine leakage.
- Illness or disease. Diabetes can greatly increase urine volume, making some individuals prone to incontinence. Other illnesses may temporarily impair the ability to recognize and control the urge to urinate or to reach the toilet in time to do so.
- Medications and alcohol. Medications that sedate, such as tranquilizers and sleeping pills, can interfere with the proper functioning of the urethral nerves and bladder. Both sedatives and alcohol can also impair an individual's ability to recognize the need to urinate and act on that need in a timely manner. Other medications, such as diuretics, muscle relaxants, and blood pressure medication, can also affect bladder function.
- Surgery. Men who undergo prostate surgery can suffer from temporary stress incontinence as a result of damage to the urethral outlet.

Diagnosis

Urinary incontinence may be diagnosed by a general practitioner, urologist, or gynecologist. If the patient is over age 65, a geriatrician may diagnose and treat the condition. A thorough medical history and **physical examination** is typically performed, along with specific diagnostic testing to determine the cause of the incontinence. Diagnostic testing may include x rays, **ultrasound**, urine tests, and a physical examination of the pelvis. It may also include a series of exams that measure bladder pressure and capacity and the urinary flow (urodynamic testing). The patient may also be asked to keep a diary to record urine output, frequency, and any episodes of incontinence over a period of several days or a week.

Treatment

There are numerous invasive and noninvasive treatment options for urinary incontinence:

- Behavior modification therapy. Behavior modification is a psychological approach to the treatment of urinary incontinence in which patients gradually increase the length of the time interval between voidings and "retrain" the bladder in other ways. It is reported to be highly effective in treating urge incontinence.
- Biofeedback. The use of sensors to monitor temperature and muscle contractions in the vagina to help incontinent patients learn to control their pelvic muscles.
- Collagen injections. Collagen injected in the tissue surrounding the urethra can provide urethral support for women suffering from stress incontinence.
- External occlusive devices. A new single-use disposable urethral cap is available without a prescription for women suffering from stress urinary incontinence. The cap is noninvasive and appears to be quite effective in managing incontinence.
- Inflatable urethral insert. Sold under the trade name Reliance, this disposable incontinence balloon for women is inserted into the urethra and inflated to prevent urine leakage.
- Intermittent urinary catheterization. The periodic insertion of a catheter into a patient's bladder to drain urine from the bladder into an attached bag or container.
- Medication. Estrogen hormone replacement therapy can help improve pelvic muscle tone in postmenopausal women. Other medications, including flurbiprofen, capsaicin, and botulinum toxin, are sometimes prescribed to relax the bladder muscles or to tighten the urethral sphincter.
- Pelvic toning exercises. Exercises to tone the pelvic muscle can help alleviate stress incontinence in both men and women. These exercises involve tightening the muscles of the pelvic floor and are also known as Kegel or PC muscle exercises.
- Perineal stimulation. Perineal stimulation is used to treat stress incontinence. The treatment uses a probe to deliver a painless electrical current to the perineal area muscles. The current tones the muscle by contracting it.
- Permanent catheterization. A permanent, or indwelling, catheter may be prescribed for chronic incontinence that does not respond to other treatments. A Foley catheter is usually used for urinary catheterization. One end is inserted through the urethra and into the bladder, and the external end is attached to a plastic reservoir bag that the patient may wear on the leg. A second alternative is a permanent catheter, called a suprapubic tube, surgically inserted into the bladder. The tube exits the body through the abdomen near the pubic bone, where it is attached to a drainage bag. As infection may result, this treatment should be reevaluated periodically, and the possibility of alternative treatment addressed.
- Sacral nerve stimulation (SNS). Also known as sacral neuromodulation, SNS is a procedure in which a surgeon implants a device that sends continuous stimulation to the sacral nerves that control the urinary sphincter. The FDA approved sacral nerve

stimulation for the treatment of urinary urge incontinence in 1997 and for urinary frequency in 1999.

- Surgery. Bladder neck suspension surgery is used to correct female urinary stress incontinence. Surgical techniques such as the Marshall-Marchetti-Krantz and Burch procedures use sutures to raise and support the bladder neck and urethra. A sling procedure, which uses a strip of biocompatible material or the patient's own muscle or tissue as a supportive sling under the urethra and bladder neck, may also be used to treat stress incontinence. Bladder enlargement surgery may be recommended to treat incontinent men and women with unusually small bladders.
- Urinary sphincter implant. An artificial urinary sphincter may be used to treat incontinence in men and women with urinary sphincter impairment.
- Vaginal inserts. Devices constructed of silicone or other pliable materials that can be inserted into a woman's vagina to support the urethra.

Prognosis

Left untreated, incontinence can cause physical and emotional upheaval. Individuals with long-term incontinence suffer from urinary tract infections, and skin **rashes** and sores. Incontinence can also affect their self-esteem and cause depression and social withdrawal. They frequently stop participating in physical activities they once enjoyed because of the risk of embarrassing "accidents." However, with the wide variety of treatment options for incontinence available today, the prognosis for incontinent patients is promising. If incontinence cannot be stopped, it can be improved in the majority of cases.

Prevention

Women who are pregnant or who have gone through **childbirth** can reduce their risk for stress incontinence by strengthening their perineal area muscles with Kegel exercises. Men who have undergone prostate surgery may also benefit from pelvic muscle exercises. Men and women should consult with their doctor before initiating any type of **exercise** program.

Urinary tract infection

Definition

A urinary tract infection (UTI) is a bacterial infection in any part of the urinary tract—the urethra, bladder, ureters, or kidneys.

Demographics

UTIs are not uncommon in children. Approximately 1% of boys and 3% of girls develop a symptomatic UTI before the age of 11. During the first year of life, uncircumcised boys are two and half times as likely as girls to develop a UTI. However after the first year, girls are 20 times as likely as boys to develop UTIs. Girls are particularly susceptible to UTIs around the age of three as toilet training begins. The incidence of UTIs in both boys and girls decreases with age.

Description

The urinary tract produces and discharges urine from the body. It includes the kidneys, ureters, bladder, urethra, and, in males, the prostate. Urine, consisting of water and waste products, is produced by the

WWW.BOOKBAZ.IR

kidneys and carried through the ureters to the bladder for storage. The urethra carries the urine from the bladder to the outside of the body. In males the urethra carries the urine through the prostate and out through the penis. The urethra in females is shorter and opens to the outside in front of the vaginal opening.

Urine is normally sterile, meaning that it is free from infectious organisms such as bacteria. The urinary tract has various mechanisms for protecting itself from infection:

- Urine has antibacterial properties.
- Urine is prevented from backing up in the ureters to the kidneys.
- The bladder secretes a protective coating that prevents bacteria from attaching to its lining.
- The flow of urine flushes bacteria from the body.

Infection can occur when bacteria attach to the opening of the urethra and enter the urinary tract. A UTI causes an inflammatory response in the lining of the urinary tract (the urothelium). Infections can affect the urethra (**urethritis**) and/or the bladder (**cystitis**). Untreated UTIs can reach the kidneys and cause a serious medical condition called **pyelonephritis**. However, in children most UTIs are restricted to the bladder.

Risk factors

A major risk factor for UTIs in girls is wiping from back to front (anus to urethral opening) after using the toilet. Other risk factors for UTIs in children include:

- previous UTIs
- infrequent or inadequate urination
- constipation in which a hard stool in the bowel presses against the urinary tract and impedes the flow of urine
- poor growth
- bubble baths
- tight–fitting clothing
- a family history of kidney disease
- birth defects in the urinary tract, especially vesicoureteral reflux—a defect in the valves between the ureters and the bladder that allows urine to back up into the ureters and kidneys
- a growth (mass) in the abdomen
- central nervous system disorders—such as myelomeningocele, spinal cord injury, or hydrocephalus—that make it difficult for children to completely empty their bladders

A susceptibility to UTIs often carries on into adulthood. In at least some cases, this susceptibility appears to be inherited.

Causes and symptoms

UTIs are caused by bacteria that enter the urinary tract. These bacteria are normally are found on the skin around the anus and sometimes around the vagina in girls or come from stool after a bowel movement. More than 95% of UTIs in children are caused by Enterobacteriaceae, a family of bacteria that includes *Escherichia coli* (*E. coli*), *Klebsiella* sp., *Proteus* sp., *Pseudomonas* sp., or *Enterococcus* sp.

Although some children are simply more susceptible to UTIs than others, the most common causes of bacteria entering a child's urinary tract are:

- girls wiping from back to front after using the toilet
- delayed urination
- failure to completely empty the bladder

Although young children with UTIs often have no symptoms, when symptoms are present they may include:

- fever, especially a recurring fever with no apparent cause
- poor appetite or refusal to eat
- fussiness or irritability
- diarrhea
- vomiting
- cloudy or foul–smelling urine
- blood in the urine

Symptoms of UTIs in older children may include:

- pain or burning during urination
- frequent urination
- bedwetting or daytime wetting
- dark or cloudy urine
- blood in the urine
- stomach or back pain

Additional symptoms of a bladder infection in children include:

- strong–smelling urine
- frequent or urgent need to urinate
- a general feeling of illness (malaise)
- pain or pressure in the lower back or lower pelvis

UTIs that spread to the kidneys can cause pyelonephritis. Symptoms of pyelonephritis include:

- fever
- flushed, red, or warm skin
- pain in the lower back or side
- severe belly pain
- nausea and vomiting
- shaking chills

KEY TERMS

Bacteriuria—The presence of bacteria in the urine.

Bladder—The elastic, muscular pouch in which urine collects before being discharged from the body through the urethra.

Catheter—A hollow, flexible tube that is inserted into a body cavity, duct, or vessel for the passage of fluids or to distend a passageway.

Cystitis—Inflammation of the bladder.

Inflammatory response—The immune system's response to tissue injury caused by a physical, chemical, or biological substance.

Kidneys—The pair of bean–shaped organs, located below the ribs toward the middle of the back, which cleanse the blood, regulate acid concentration, and maintain water balance in the body through the formation of urine.

Prostate—The walnut–shaped gland that surrounds the urethra at the neck of the bladder in males and supplies fluid for semen.

Pyelonephritis—Bacterial infection of the kidney.

Sterile—Free from infectious organisms such as bacteria.

Ureters—The tubes that drain urine from the kidneys to the bladder.

Urethra—The tube that discharges urine from the bladder to the outside of the body. In males the urethra is located in the penis. In females the urethra is shorter than in the males and emerges above the vaginal opening.

Urethritis—Infection of the urethra.

Urinary tract—The organs that produce and discharge urine, including the kidneys, ureters, bladder, and urethra.

Urine—The fluid containing water and waste products that is produced by the kidneys, stored in the bladder, and removed from the body through the urethra.

Urothelium—The lining of the urinary tract, including the renal pelvis, ureters, bladder, and urethra.

Diagnosis

Examination

Clinical signs and symptoms are usually suggestive of a UTI. The child will be checked for **fever** and the physician will examine the child's abdomen and lower back for masses, bladder swelling, and unusual enlargement of the kidneys.

Tests

UTIs are diagnosed by **urinalysis**. A urine sample is collected by having the child urinate into a cup. If a child is still using diapers, the area around the urethra is cleansed with soap and warm water or a sterile wipe, and a collection bag is held in place over the urethral opening with adhesive strips. Sometimes urine is collected from infants and toddlers by inserting a catheter—a thin plastic tube—into the urethra to collect urine directly from the bladder. A suprapubic urine collection is performed by inserting a needle through the skin and muscles of the lower abdomen into the bladder.

The urine sample is examined under a microscope or tested with dipsticks for the presence of bacteria (bacteriuria), red blood cells, and white blood cells that indicate an immune system response to infection. The urine sample may be sent to a laboratory for culturing to determine the type of bacteria and the appropriate antibiotic for treatment. Additional blood tests may be performed to diagnose a kidney infection.

Procedures

Imaging procedures are sometimes performed to determine whether UTIs are caused by urinary reflux or another problem that is blocking urine flow. Imaging is also used to diagnose kidney damage. Although imaging may be performed while the child has a UTI, it is more often done after the infection has cleared up. Procedures include:

- ultrasound of the urinary tract
- a cystourethrogram—an x ray of the bladder and urethra, taken after injection of a contrast dye, to detect structural abnormalities
- a voiding cystourethrogram—an x ray taken while the child is urinating
- intravenous pyelogram for obtaining x-ray images of the bladder, kidneys, and ureters
- cystoscopy—in which a thin tube called a cystoscope, containing a light and a camera, is inserted through the urethra to examine the inside of the bladder and ureters and possibly remove a small amount of tissue for examination by a pathologist
- computed tomography (CT) scans to detect a kidney infection or cancer in the urinary tract

Treatment

Traditional

UTIs are treated immediately with **antibiotics** to protect the child's developing kidneys from infection.

WWW.BOOKBAZ.IR

However urinary reflux or other structural problems may require surgery. Urinary reflux is sometimes treated by cutting one or both ureters away from the bladder and reattaching them at a different angle to prevent urine from backing up. Urinary reflux may also be treated by injecting a bulking agent around the ureter opening so that urine can flow into the bladder but is prevented from backing out.

Drugs

UTIs are usually treated immediately with oral antibiotics against the most common bacteria. Sometimes the type of antibiotic is changed after laboratory results have identified the specific bacterium. Most antibiotics are taken for 9 to 10 days, although some may require a two–week course of treatment. Young infants may require intravenous antibiotics that are administered in a hospital. Some children with recurrent UTIs are treated with antibiotics for as long as six months to two years. The most common antibiotics for treating UTIs in children include:

- amoxicillin (Amoxil, Trimox, Wymox) or amoxicillin/clavulanic acid (Augmentin)
- cephalosporins
- nitrofurantoin (Macrodantin, Furadantin)
- trimethoprim–sulfamethoxazole (TMP/SMZ; Bactrim, Septra, Cotrim)
- doxycycline, in children aged eight and older

Alternatives

Although UTIs in children must be treated with antibiotics to prevent kidney damage, antimicrobial herbal therapies include:

- garlic (*Allium sativum*)
- goldenseal (*Hydrastis canadensis*)
- bearberry (*Arctostaphylos uva–ursi*)

Other alternative treatments for UTIs include:

- demulcents, such as corn silk and marsh mallow (*Althaea officinalis*), to soothe and coat the urinary tract
- homeopathic medicines based on the child's symptoms
- Chinese traditional medicine
- acupuncture

Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

Home remedies

The most important home remedy for a UTI is drinking plenty of fluids, especially water. Other home treatments include:

- unsweetened cranberry juice, which has antibacterial activity
- ascorbic acid (vitamin C), which increases acidity of the urine
- eliminating all sugar from the diet
- avoiding soft drinks with caffeine, citrus juices, spicy foods, coffee, and alcohol
- applying a heating pad to the lower abdomen
- soaking the pelvis in warm or hot water (a sitz bath) for 15–20 minutes

Prognosis

UTIs in children are usually readily cured with antibiotics and have an excellent prognosis, although they may require long–term treatment with low–dose antibiotics. A new antibiotic–resistant strain of *E. coli* is increasingly difficult to treat. Almost 26% of infants with symptomatic UTIs have a recurrence, usually within three months. About 40–60% of older girls with a UTI will also have a recurrence. However most children outgrow urinary reflux problems.

Repeated UTIs in children can damage their kidneys. Scarring of the kidneys is the fourth–leading cause of **kidney transplantation** in children. Long–term complications of repeated UTIs may include:

- pyelonephritis
- an abscess in a kidney
- high blood pressure
- kidney swelling (hydronephrosis)
- kidney insufficiency or failure

Prevention

Although some highly susceptible children may require long–term preventive antibiotic treatment, most UTIs in children can be prevented by good toilet hygiene:

- urinating regularly, whenever the child feels the urge, and never holding in urine
- emptying the bladder completely
- wiping from front to back, away from the urethra, especially after a bowel movement
- keeping the genital area clean

Other practices for preventing UTIs in children include:

- drinking plenty of fluids, especially water
- avoiding tight–fitting clothes that trap moisture and encourage bacterial growth
- wearing only cotton underwear that allows air in to dry out the genital area

- avoiding bubble bath and any other irritating products in the genital area
- taking showers rather than baths
- monitoring urination patterns in young children
- having older children notify their parents if urination becomes painful
- treating constipation
- drinking cranberry juice or taking vitamin C

Urine culture

Definition

A urine culture is a diagnostic laboratory test performed to detect the presence of bacteria in the urine (bacteriuria).

Purpose

Culture of the urine is a method of diagnosis for **urinary tract infection** (UTI) that determines the number of microorganisms present in a given quantity of urine.

Description

There are several different methods for collection of a urine sample. The most common is the midstream clean-catch technique. Hands should be washed before beginning. For females, the external genitalia (sex organs) are washed two or three times with a cleansing agent and rinsed with water. In males, the external head of the penis is similarly cleansed and rinsed. The patient is then instructed to begin to urinate, and the urine is collected midstream into a sterile container. In infants, a urinary collection bag (plastic bag with an adhesive seal on one end) is attached over the labia in girls or the penis in boys to collect the specimen.

Another method is the catheterized urine specimen, in which a lubricated catheter (thin rubber tube) is inserted through the urethra and into the bladder. This avoids contamination from the urethra or external genitalia. If the patient already has a urinary catheter in place, the specimen may be collected by clamping the tubing below the collection port and using a sterile needle and syringe to obtain the urine sample; urine cannot be taken from the drainage bag, as it is not fresh and has had an opportunity to grow bacteria at room temperature. On rare occasions, the healthcare provider may collect a urine sample by inserting a needle directly into the bladder (suprapubic tap) and draining the urine; this method is used only when a sample is needed quickly.

WWW.BOOKBAZ.IR

KEY TERMS

Bacteriuria—The presence of bacteria in the urine.

Urethra—The tube that carries urine from the bladder to outside the body. In females, the urethral opening is between the vagina and clitoris; in males, the urethra travels through the penis, opening at the tip.

Negative culture results showing no bacterial growth are available after 24 hours. Positive results require 24–72 hours to complete identification of the number and type of bacteria found.

Precautions

If delivery of the urine specimen to the laboratory within one hour of collection is not possible, it should be refrigerated. The healthcare provider should be informed of any **antibiotics** currently or recently taken.

Preparation

Drinking a glass of water 15–20 minutes before the test is helpful if there is no urge to urinate. There are no other special preparations or aftercare required for the test.

Aftercare

No aftercare is required for a urine culture.

Risks

There are no risks associated with the culture test itself. If insertion of a urinary catheter (thin rubber tube) is required to obtain the urine, there is a slight risk of introducing infection from the catheter.

Results

No growth of bacteria is considered the normal result, and this indicates absence of infection.

Abnormal results

Abnormal results, or a positive test, where bacteria are found in the specimen, may indicate a UTI. Contamination of the specimen from hair, external genitalia, or the rectum may cause a false-positive result. Identification of the number and type of bacteria, with consideration of the method used in obtaining the specimen, is important for diagnosis.

Escherichia coli causes approximately 80% of infections in patients without catheters, abnormalities of the urinary tract, or calculi (stones). Other bacteria that account for a smaller portion of uncomplicated infections include *Proteus, Klebsiella*, and *Enterobacter*.

Urine flow test

Definition

A urine flow test evaluates the speed of urination, or amount voided per second, and the total time of urination.

Purpose

A urine flow test is utilized to determine bladder function abnormalities, including a narrowed or obstructed urethra (the outflow passage from the bladder) and a weakened bladder muscle (detrusor).

KEY TERMS

Detrusor muscle—Bladder muscle.

Urethra—Passageway that carries urine from the bladder.

Description

During a urine flow test, the patient urinates into a uroflowmeter, a funnel-shaped device that reads, measures, and computes the rate and amount of urine flow. The test takes approximately 10 minutes.

Preparation

The patient is prohibited from urinating at least two hours before the procedure.

Results

Average urine flow rates vary depending on age and gender.

Abnormal results

A urine flow test can indicate problems in bladder function, such as an obstruction, that will need further tests to diagnose.

Uterine fibroid embolization

Definition

Uterine fibroids are growths in the muscular tissue of the womb (uterus). Uterine fibroid embolization is non-surgical removal of the growths through the use of a tubular device called a catheter.

Purpose

It is estimated that between 20% and 40% of women over age 35 years have fibroids. These non-cancerous tumors of the uterus, also called myomas, fibromyomas, or leiomyomas, can be as tiny as a pea or grow to as large as a cantaloupe. They grow along the muscular wall of the uterus and are made of both muscle and fiber-like tissue. Although they are not cancerous, they can cause uncomfortable symptoms in women, particularly **pain** and a feeling of pressure in the area between the hip bones (the lower pelvic area). Some women experience a feeling that they constantly need to urinate. Others may feel pressure in the bowel and experience bloating or **constipation**. Sometimes, fibroids cause heavy menstrual bleeding and lengthier menstrual periods.

In some cases, women need no treatment for fibroids, since the growths may cause no symptoms or may stop causing symptoms when a woman reaches **menopause**. However, when the fibroids cause heavy bleeding that can lead to anemia, pelvic pain, and create pressure on other organs, the physician and patient may discuss treatment options. A woman still planning to have children may need to have fibroids removed to ensure they do not interfere with the ability of a fertilized egg to implant on her uterine lining. In rare cases, fibroids cause such severe and sharp pelvic pain that emergency treatment is required.

Although some medications may help ease the symptoms of fibroids or even slow their growth, they are not long-term solutions to the fibroid growths. Surgery also can remove the fibroids. **Myomectomy** is the most common surgery option still used to treat fibroids because it does not involve removing the uterus. In severe cases, women may have a **hysterectomy** and have their uterus removed.

The development of uterine fibroid embolization has offered women a non-surgical alternative to treating fibroids that are causing symptoms. It also is effective for treating multiple fibroids.

Precautions

Although uterine fibroid embolization has been shown in many studies to be effective, some physicians say it is a relatively new procedure that lacks long-term data on its effectiveness. Estimates show that at least 90% of women who have the procedure will have relief of symptoms and no return of fibroids. Some women have reportedly stopped having menstrual periods following the procedure. Since the long-term effects of uterine fibroid embolization on future pregnancies has not been studied extensively, patients still wanting

WWW.BOOKBAZ.IR

to have children should discuss the latest research and fibroid treatment options with their physicians. Overall, however, the treatment is a safer and less invasive alternative than surgery.

Description

Uterine fibroid embolization usually is performed in a hospital, but sometimes in an outpatient imaging center. An interventional radiologist normally performs the procedure. Interventional radiologists are physicians who are specially trained to use x rays to see inside the body while guiding narrow tubes called catheters through blood vessels to diagnose or treat various diseases.

Uterine fibroid embolization also may be called uterine artery embolization. This is because the procedure injects tiny particles, called embolic agents, into the artery that supplies blood to the fibroid tumor, blocking off the tumor's blood supply. The radiologist reaches the uterine artery by first making a small nick (about one-quarter of an inch) in the patient's skin in the groin area. From this incision, the radiologist can inset the catheter into the femoral artery and then guide the catheter toward the area of the uterus. Patients do not feel the catheter as it moves along the artery and a nurse or anesthesiologist will provide drugs for pain relief at the insertion site. The nurse or a technologist also will insert a Foley catheter into the patient's bladder. This keeps the bladder emptied so that the radiologist can have a better picture of the uterus and the anatomy that surrounds the uterus during the procedure.

The radiologist can view the progress of the catheter using a moving x-ray technique called fluoroscopy. When the catheter reaches the artery supplying blood to the fibroid tumor, the radiologist injects the embolic agents, which are only about the size of grains of sand. When they gather together, they form a clot, and since no more blood can reach the fibroids, they eventually will shrink and disappear. If a woman has fibroids on both sides, the radiologist will guide the catheter around to repeat the procedure on the other side of the uterus. After removing the catheter, the medical team will clean the puncture area and cover it with a bandage. They also remove the Foley catheter. The entire procedure takes about one hour and should cost less than hysterectomy or other surgical treatments. Most insurance companies will pay for uterine fibroid embolization.

Preparation

When the embolization is scheduled, the hospital or facility should provide instructions regarding medications or food and drink to avoid prior to the procedure.

KEY TERMS

Anemia—A condition in which the blood has a low number of red blood cells, low hemoglobin, or low total blood volume.

Artery—One of several tubular branches of muscular and elastic walled vessels that carry blood from the heart through the body.

Femoral artery—The chief artery of the thigh.

Groin—The fold that marks the meeting of the lower abdomen and the inner thigh.

Once a patient checks in, a nurse or technician may draw blood for routine tests and a nurse or radiologic technologist who specializes in vascular procedures will start an intravenous (IV) line through which the patient will receive **antibiotics** to prevent infection.

Aftercare

Although uterine fibroid embolization is an outpatient procedure, patients may stay in a recovery area for up to 23 hours. When patients are discharged, they will receive specific instructions about follow-up care and medication for relief of pain and swelling. Uterine fibroid embolization rarely requires stitches. Patients may be advised to use a stool softener while taking some of the aftercare medications to avoid constipation. They will be instructed to drink plenty of fluids for the first week following the procedure. Normally, the patient should avoid soaking in hot baths for the first three days and should not drive a car for about three days following uterine fibroid embolization.

Strenuous activity, such as climbing stairs, squatting, or lifting heavy objects should be avoided for about one week. Patients also should not stand in one position for long periods of time in the first week following the procedure. It is usually best to avoid heavy **exercise** routines, athletic activity and sexual relations for about up to month. Women also may be advised to avoid using tampons for menstrual periods for up to three months following uterine fibroid embolization, substituting sanitary pads.

Risks

Most patients experience moderate to severe pain and cramping for several hours after the procedure and some will have nausea and **fever**. There is a risk of infection from uterine fibroid embolization, but the risk is small and the infection usually can be controlled by

antibiotics. A small percentage (about 1%) of women may experience an injury to the uterus or an infection that may lead to a later hysterectomy. There also is a small risk that a woman will stop having periods after uterine fibroid embolization. Overall, these risks are relatively low compared to surgical removal of fibroids.

Results

About 90% of women who have the procedure experience significant or complete relief of heavy bleeding, pain, and other symptoms. Patients usually will follow up with their gynecologist about two weeks following the procedure. Recurrence of fibroids is rare, though long-term studies of 10 years or more have shown that about 10% of patients may need additional treatment after 10 years. Additional studies continue on the procedure's long-term effectiveness.

Uterine fibroids

Definition

Uterine fibroids (also called leiomyomas or myomas) are benign growths of muscle inside the uterus. They are not cancerous, nor are they related to cancer. Fibroids can cause a wide variety of symptoms, including heavy menstrual bleeding and pressure on the pelvis.

Demographics

Uterine fibroids are extremely common. About 25% of women in their reproductive years have noticeable fibroids. There are probably many more women who have tiny fibroids that are undetected.

Fibroids develop between the ages of 30 and 50. They are never seen in women less than 20 years old. After **menopause**, if a woman does not take estrogen, fibroids shrink. It appears that African–American women are much more likely to develop uterine fibroids.

Description

Fibroids are divided into different types, depending on the location. Submucous fibroids are found in the uterine cavity; intramural fibroids grow on the wall of the uterus; and subserous fibroids are located on the outside of the uterus. Many fibroids are so large that they fit into more than one category. The symptoms caused by fibroids are often related to their location.

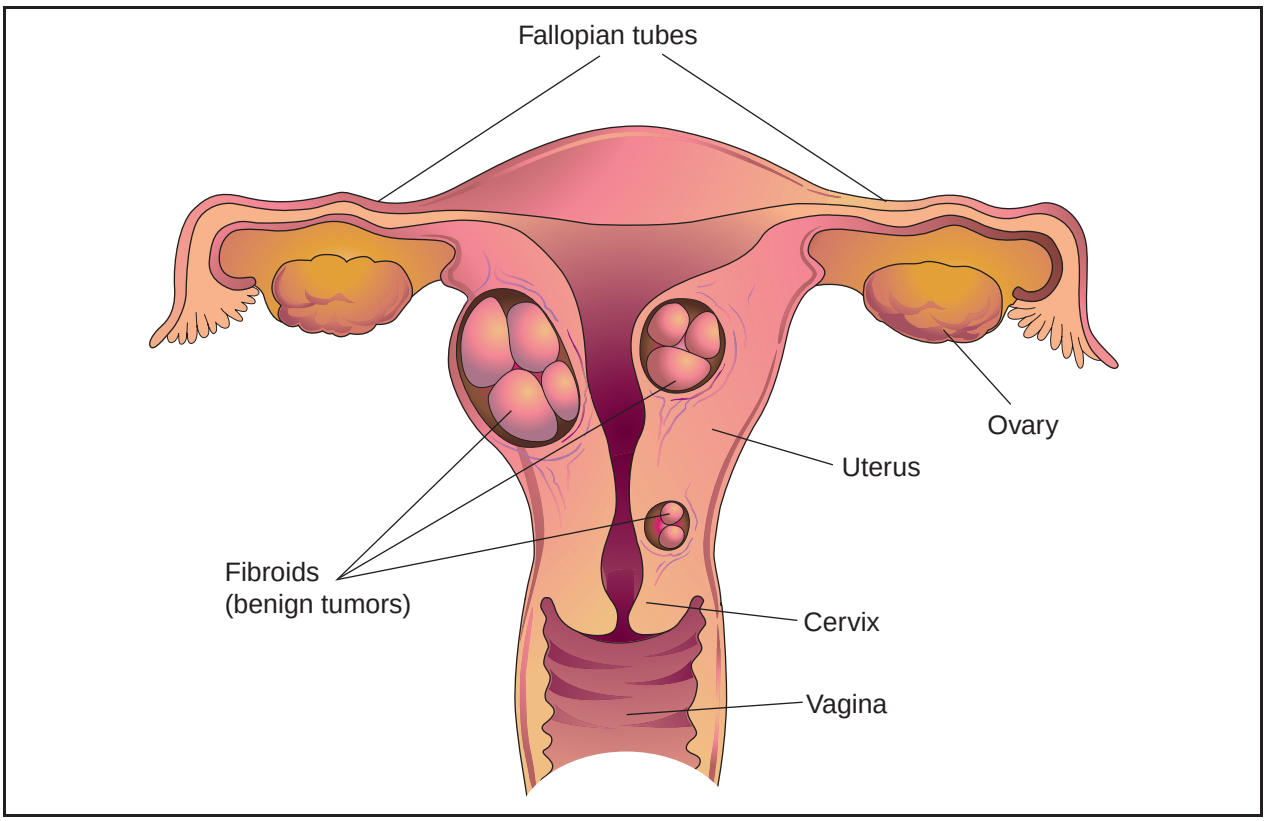
Causes and symptoms

No one knows exactly what causes fibroids. However, the growth of fibroids appears to depend on the hormone estrogen. Fibroids often grow larger when estrogen levels are high, as in **pregnancy**. Medications that lower the estrogen level can cause fibroids to shrink.

The signs and symptoms of fibroids include:

- Heavy uterine bleeding. This is the most common symptom, occurring in 30% of women who have fibroids. The excess bleeding usually happens during the menstrual period. Flow may be heavier, and periods may last longer. Women who have submucous or intramural fibroids are most likely to have heavy uterine bleeding.
- Pelvic pressure and pain. Large fibroids that press on nearby structures such as the bladder and bowel can cause pressure and pain. Larger fibroids tend to cause worse symptoms.
- Infertility. This is a rare symptom of fibroids. It probably accounts for less than 3% of infertility cases. Fibroids can cause infertility by compressing the uterine cavity. Submucous fibroids can fill the uterine cavity and interfere with implantation of the fertilized egg.
- Miscarriage. This is also an unusual symptom of fibroids, probably accounting for only a tiny fraction of the miscarriages that occur.

WWW.BOOKBAZ.IR



Uterine fibroids are benign growths of uterine muscle and are very common. They are divided into three types, depending on the location. Submucous fibroids are found in the uterine cavity; intramural fibroids grow on the wall of the uterus; and subserous fibroids are located outside of the uterus. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

- Pregnancy complications. Fibroids can greatly increase in size during pregnancy, because of increased levels of estrogen. They can cause pain and even lead to premature labor.

Diagnosis

A healthcare provider can usually feel fibroids during a routine pelvic examination. **Ultrasound** can be used to confirm the diagnosis, but this is not necessary.

Treatment

Not all fibroids cause symptoms. Even fibroids that do cause symptoms may not require treatment. In the majority of cases, symptoms are inconvenient and unpleasant, but do not result in health problems.

Occasionally, fibroids lead to such heavy menstrual bleeding that the woman becomes severely anemic. In these cases, treatment of fibroids may be necessary. Very large fibroids are much harder to treat. Therefore, many doctors recommend treatment for moderately–sized fibroids, in the hopes of preventing them from growing into large fibroids that cause worse symptoms.

The following are possible treatment plans:

- Observation. This is the most common plan. Most women already have symptoms at the time their fibroids are discovered, but feel that they can tolerate their symptoms. Therefore, no active treatment is given, but the woman and her physician stay alert for signs that the condition might be getting worse.
- Hysterectomy. This involves surgical removal of the uterus, and it is the only real cure for fibroids. In fact, 25% of hysterectomies are performed because of symptomatic fibroids. By the time a woman has a hysterectomy for fibroids, she has usually endured several years of worsening symptoms because fibroids tend to grow over time. A gynecologist can remove a fibroid uterus during either an abdominal or a vaginal hysterectomy. The choice depends on the size of the fibroids and other factors such as previous births and previous surgeries.
- Myomectomy. In this surgical procedure only the fibroids are removed; the uterus is repaired and left

KEY TERMS

Anemia—Low blood count.

GnRH antagonists—A group of medications that affect the reproductive hormones. These medications are used to treat fibroids, endometriosis, and infertility.

Hysterectomy—Removal of the uterus (with or without removal of the ovaries) by surgery. The surgery can be performed through an incision in the abdomen, or the uterus can be removed through the vagina.

Menopause—The end of the reproductive years, signaled by the end of menstrual periods. Also known as "the change."

Osteoporosis—A bone disorder in which the bones become gradually less dense and more brittle.

in place. This is the surgical procedure many women choose if they are not finished with childbearing. At first glance, it seems that this treatment is a middle ground between observation and hysterectomy. However, myomectomy is actually a difficult surgical procedure, more difficult than a hysterectomy. Myomectomy often causes significant blood loss, and blood transfusions may be required. In addition, some fibroids are so large, or buried so deeply within the wall of the uterus, that it is not possible to save the uterus, and a hysterectomy must be done, even though it was not planned. There are exceptions to this, however. Sometimes, fibroids grow on a stalk (pedunculated fibroids), and these are easy to remove.

- Medical treatment. Since fibroids are dependent on estrogen for their growth, medical treatments that lower estrogen levels can cause fibroids to shrink. A group of medications known as GnRH antagonists can dramatically lower estrogen levels. Women who take these medications for three to six months find that their fibroids shrink in size by 50% or more. They usually experience dramatic relief of their symptoms of heavy bleeding and pelvic pain.

Unfortunately, GnRH antagonists cause unpleasant side effects in over 90% of women. The therapy is usually used for only three months, and should not be used for more than six months because the risk of developing brittle bones (**osteoporosis**) begins to increase. Once treatment is stopped, fibroids begin to grow back to their original size. Within six months, most of the old symptoms return. Therefore, GnRH agonists cannot be used as long–term solution. At the moment, treatment with GnRH antagonists is used mainly in preparation for surgery (**myomectomy** or **hysterectomy**). Shrinking the size of fibroids makes surgery much easier, and reducing heavy bleeding allows a woman to build up her blood count before surgery.

Fibroids can cause problems during pregnancy because they often grow in size. Large fibroids can cause **pain** and lead to **premature labor**. Fibroids cannot be removed during pregnancy because of the risk of injury to the uterus and hemorrhage. GnRH antagonists cannot be used during pregnancy. Treatment is limited to pain medication and medication to prevent premature labor, if necessary.

Prognosis

Many women who have fibroids have no symptoms or have only minor symptoms of heavy menstrual bleeding or pelvic pressure. However, fibroids tend to grow over time, and gradually cause more symptoms. Many women ultimately decide to have some form of treatment. Currently, hysterectomy is the most popular form of treatment.

Prevention

Uterine fibroids cannot be prevented.

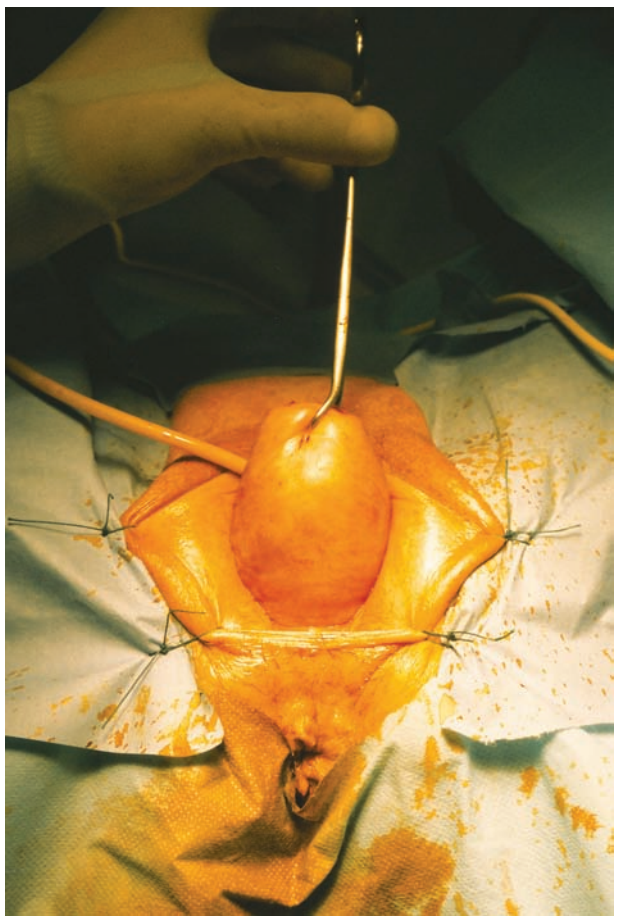
Uterine prolapse

Definition

Uterine prolapse is a type of pelvic organ prolapse that occurs when pelvic muscles and ligaments weaken and allow the uterus (womb) to bulge into the vagina.

Description

Normally the uterus is held in place by muscles and ligaments. However, when these muscles and ligaments weaken, the uterus can slip down into the vagina. The uterus is not the only pelvic organ that can bulge into the vagina. The bladder, small intestine, and rectum can also cause vaginal bulges either independently or along with a uterine prolapse.



A prolapsed uterus occurs when the uterus protrudes through the vagina due to a weakening of the organ's support ligaments. *(DELALANDE / BSIP SA / Alamy)*

Uterine prolapses are classified as follows.

- First degree: the cervix (lower part of the uterus) slightly protrudes into the vagina.
- Second degree: the cervix drops into the vagina.
- Third degree: the cervix protrudes outside the vagina.
- Fourth degree, also called procidentia: the entire uterus is outside the vagina.

Risk factors

The risk of developing a uterine prolapse increases with the number of vaginal deliveries during **childbirth**. Delivering large babies is also a risk factor, as are frequent heavy lifting, decreased estrogen levels that accompany **menopause**, **obesity**, **chronic obstructive pulmonary disease** (COPD), chronic coughing, chronic **constipation**, severe straining to have a bowel movement, and genetic abnormalities of connective tissue (uncommon). Prior pelvic surgery also increases the risk of developing a uterine prolapse.

Demographics

Many uterine prolapses are mild and cause no or minor symptoms, so the exact frequency is difficult to determine. The frequency of uterine prolapses increases with age. About half of all women over age 50 years have some degree of pelvic organ prolapse, not all of which are uterine prolapses. Between 10% and 20% of these prolapses cause noticeable symptoms. Uterine prolapses are the second most common prolapses after bladder prolapses (also called cystoceles). Hispanic and white women are more likely to develop uterine prolapses than women of other races.

Causes and Symptoms

Uterine prolapse is caused by a weakening of the pelvic floor muscles and the ligaments that hold the uterus in place. Pregnancies, especially difficult labors and vaginal deliveries of large babies, are the most common cause of uterine prolapse. **Trauma** from heavy lifting, increasing age, genetic abnormalities, and rarely pelvic tumors also can cause uterine prolapse.

Mild uterine prolapse often causes no symptoms. More severe prolapse can cause:

- a feeling of pressure or heaviness in the pelvic area
- feeling as if something is falling out of the vagina
- difficulty urinating or loss of urinary control
- difficulty having a bowel movement
- tissue protruding into the vagina that the woman can feel
- low back pain

Symptoms may worsen with standing or walking as gravity pulls on the tissue bulging into the uterus.

Diagnosis

Uterine prolapse is diagnosed by an internal pelvic examination. A **Pap test** usually is performed at the same time. If surgery is considered to correct the problem, an **ultrasound** and standard presurgical tests will be performed.

Treatment

Many uterine prolapses are mild and need no treatment. Other more severe prolapses that cause significant symptoms are treated conservatively or with surgery. The type of treatment depends on the woman's age, childbearing plans, degree of prolapse, and intensity of symptoms.

Conservative treatment

Conservative treatment consists of the placement of a vaginal pessary. A pessary is a device inserted into the vagina to give it more support. There are many types of pessaries. The physician will measure and fit the device. Sometimes it takes trial and error to find the correct pessary for an individual. The pessary is not permanent. Women can learn to remove and re-insert the device to allow sexual intercourse.

Surgery

Pessaries are often inadequate to treat severe prolapses. In this case, surgery may be required. There are two types of surgery used to treat uterine prolapses. Obliterative surgery closes off the vagina. This provides support for the pelvic organs, but makes sexual intercourse impossible. This type of surgery is most often used in the elderly.

Reconstructive surgery restores the uterus to its correct position and then strengthens the pelvic floor. Some types of reconstructive surgery can be done as laparoscopic surgery, while others require a larger incision. Sometimes a **hysterectomy** is done at the same time the pelvic floor is repaired.

Alternatives

Regularly performing Kegel exercises will strengthen the pelvic floor muscles and improve bladder and bowel control. These exercises are done by repeatedly contracting then relaxing the pelvic floor muscles. Although Kegel exercises will not restore the uterus to its proper position, they may help reduce symptoms.

Prognosis

Many uterine prolapses never progress beyond the mild state. Others can be worsened by additional pregnancies, heavy lifting and chronic constipation.

Prevention

There is no definite way to prevent uterine prolapse. Performing Kegel exercises and maintaining a healthy weight may reduce the likelihood of developing a prolapse, as will learning the correct way to lift and not performing repeated heavy lifting.

Uveitis

Definition

Uveitis is an inflammation of the uveal tract, which lines the inside of the eye behind the cornea. Much of the uvea lies between the retina and the tough, outer sclera. The uveal tract has three parts: the iris, the ciliary body, and the choroid. Uveitis is categorized according to the part of the uveal tract that is affected. Anterior uveitis is an inflammation of the front part of the uveal tract; it includes inflammation of the iris (iritis) and inflammation of the iris and the ciliary body (iridocyclitis). Posterior uveitis is an inflammation of the part of the uveal tract behind the lens of the eye. It includes inflammation of the choroid (choroiditis) and inflammation of the choroid and retina (chorioretinitis). Uveitis that affects the entire uveal tract is called panuveitis or diffuse uveitis.

Description

The uveal tract is made up of the iris, ciliary body, and choroid. The iris is the colored part of the eye. The ciliary body is inside the eye and produces a fluid called aqueous humor. Ciliary muscles aid in accommodation, the process of changing the shape of the lens in the eye to see things at various distances. The choroid lines the back of the eye and has many blood vessels. It helps nourish part of the retina. The choroid lies between the retina and outermost sclera.

Uveitis may either persist for a long time (chronic) or have a short-term duration (acute). Anterior uveitis is classified as either granulomatous or nongranulomatous. The distinction is based on the disease agents that were considered responsible for the condition. At one time, it was thought that granulomatous uveitis was caused by **tuberculosis** bacilli whereas nongranulomatous uveitis was thought to be caused by streptococci. The distinction is still used even though the causes of uveitis are now understood differently.

This person has acute iritis, or inflammation of the iris. Symptoms include pain in the eye or forehead and reddening of the margin of the iris. *(Photo Researchers, Inc.)*

In most cases, uveitis affects only one eye, although posterior uveitis sometimes involves both eyes. About 60% of cases develop within the eye itself, but 40% are associated with systemic diseases or disorders ranging from **toxoplasmosis** to **syphilis**. Many of these are diseases of childhood and adolescence. Uveitis does not appear to run in families or to be associated with lifestyle choices, occupational history, geographical location, or environmental factors.

Uveitis is a serious condition that may develop rapidly and cause lasting damage to the eye. Patients who think they may have chronic uveitis should seek evaluation and treatment by an ophthalmologist (a physician who specializes in diseases of the eye) as soon as possible. If the patient has a sudden loss of vision and the eye looks inflamed, the patient should go *immediately* to the doctor for emergency treatment.

Causes and symptoms

The causes of uveitis are not fully understood, but they can be a result of **trauma**, allergy, or a response to a systemic or ocular disease. Uveitis may be a type of immune-response mechanism. In people with impaired immune systems, uveitis may be due to an infection.

Chronic uveitis is often associated with systemic disorders (e.g., **Lyme disease**, **sarcoidosis**, or juvenile **rheumatoid arthritis**).

Anterior uveitis

The so-called classic symptoms of anterior uveitis—severe **pain**; redness, particularly around the edge of the iris; and extreme sensitivity to light (photophobia)—occur mostly in acute uveitis. In anterior uveitis, the doctor will see a so-called "flare and cell" pattern when looking into the watery fluid (aqueous humor) between the cornea and the lens of the patient's eye. The iris may adhere to the lens, thus increasing the intraocular pressure. There may be nodules on the iris. There may be tearing and the pupil may be constricted and nonreactive. In severe cases of anterior uveitis, there may be hypopyon (a small amount of pus or collection of white cells) visible when the doctor examines the eye.

GRANULOMATOUS UVEITIS. In granulomatous uveitis, there will be large yellowish-white cells visible on the back of the cornea and possibly some small

nodules on the iris. Granulomatous uveitis is usually less acute than the nongranulomatous form; the eye is only mildly inflamed and the patient's vision is somewhat blurred.

Granulomatous uveitis can be produced by syphilis, toxoplasmosis, cytomegalovirus, sarcoidosis, tuberculosis, or Vogt-Koyonagi-Harada syndrome (VKH). VKH is marked by severe uveitis associated with hair loss, **hearing loss**, loss of pigment in the eyelashes and brows, and headaches. It occurs most commonly in Asians.

NONGRANULOMATOUS UVEITIS. In nongranulomatous uveitis, the cells visible on the cornea are smaller, and there are no masses on the iris. This type of anterior uveitis is, however, more painful. The eye is red and the patient experiences both photophobia and loss of vision.

Systemic diseases that can cause nongranulomatous uveitis include **ankylosing spondylitis**, Reiter's syndrome, **psoriasis**, ulcerative **colitis**, Behcet's syndrome, Lyme disease, and Crohn's disease. Children—especially girls—with anterior uveitis should be screened for juvenile rheumatoid arthritis (JRA).

Posterior uveitis

The symptoms of posterior uveitis are sometimes subtle. The patient may notice blurred or hazy vision, or floating black spots before the eyes. There may be pain and photophobia. The iris may attach to the lens in the eye, thus increasing intraocular pressure.

Posterior uveitis may be acute or chronic. It is more likely to involve both eyes. When the doctor examines the eye, cells may be seen in the vitreous humor, which is the normally transparent gel that fills the eyeball behind the lens. There will be yellowish or dark areas of inflammation on the choroid and the retina. The blood vessels in the retina develop a sheath or covering of inflammatory tissue. In severe cases, the vitreous humor is so cloudy that the doctor cannot see the retina at the back of the eye.

PARS PLANITIS. Pars planitis is an inflammation of the pars plana, which is a part of the ciliary body. Pars planitis usually occurs in older children or young adults, and can develop into posterior uveitis.

The diseases that cause granulomatous uveitis may also cause posterior uveitis.

Diagnosis

The eye doctor will examine the patient's eyes with a slit lamp in order to rule out **conjunctivitis** and certain types of **glaucoma**. The slit lamp is an instrument that combines a binocular microscope with a special light. The slit lamp can shine a narrow beam of very bright light into the eye and allow the doctor to examine the front part of the eye in detail. The slit-lamp exam is not painful, however if the patient is sensitive to light there will be discomfort.

The absence of a discharge from the eye and the absence of infectious organisms in a laboratory smear usually rule out conjunctivitis. In addition, the size of the pupil is often small in uveitis whereas it is normal in conjunctivitis. In acute glaucoma, the patient has severe pain, the cornea of the eye is cloudy, and the pressure level of the fluid inside the eye is abnormally high, whereas in uveitis the pain is moderate, the cornea is clear, and the fluid pressure is normal or possibly lower or slightly above normal. The doctor may also use the slit lamp and another lens to examine the back of the eye to get a good look at the retina and choroid. Other instruments, such as a hand-held ophthalmoscope or a binocular indirect ophthalmoscope, can be used to examine the back of the eye. There should be no discomfort with these tests except if the patient is sensitive to the bright light.

Laboratory testing

Laboratory testing is used to rule out conjunctivitis in some patients. The doctor wipes the inside of the patient's eyelid with a swab in order to obtain a sample for testing. Although blood tests are not necessary to diagnose uveitis by itself, they are used to diagnose the cause if the doctor suspects that toxoplasmosis or another systemic disease is responsible for the uveitis.

Treatment

Uveitis is generally treated by an ophthalmologist because therapy requires topical and oral medications; however, some optometrists (O.D.) are state licensed to use therapeutic medications. Other doctors may be involved in treating the underlying disease, if the patient has one, and in monitoring the patient's responses to medications.

Anterior uveitis is treated with corticosteroid drops; in severe cases, the patient may be given steroid injections in the area of the eye or oral **steroids**. Atropine sulfate drops may be given to dilate the patient's pupil. Posterior uveitis is treated with **systemic corticosteroids**. It is usually not necessary to dilate the pupil.

Prolonged steroid use may increase intraocular pressure, thereby increasing the risk of glaucoma. Steroid use has also been connected to cataract formation. Patients should be monitored closely and frequently.

KEY TERMS

Choroid—The part of the uveal tract behind the ciliary body. The choroid underlies and nourishes the retina and absorbs scattered light.

Ciliary body—The part of the uveal tract between the iris and the choroid.

Cornea—The transparent front part of the eye that covers the iris and pupil.

Flare and cell—A pattern revealed by slit-lamp examination that indicates uveitis. Flare and cell resembles light filtered through smoke.

Hypopyon—A small amount of pus or collection of white cells that is visible in the front of the eye in severe cases of anterior uveitis.

Iris—The circular membrane that forms the colored portion of the eye and expands or contracts around the pupil.

Photophobia—Extreme sensitivity to light. Photophobia is a major symptom of acute uveitis.

Pupil—The opening in the center of the iris that allows light to pass through to the retina.

Retina—The innermost membrane at the back of the eyeball on which images are projected by the lens.

Slit lamp—An instrument that combines a binocular microscope with special lights. It allows an eye doctor to examine the front portion of the eye.

Uveal tract—The pigmented membrane that lines the back of the retina of the eye and extends forward to include the iris. The uveal tract is sometimes called the uvea and has three parts: the iris, the choroid, and the ciliary body.

Vitreous humor—The clear gel-like substance that fills the eyeball behind the lens.

Prognosis

The prognosis depends upon the location of the uveitis, on whether it is chronic or acute, and on the promptness of treatment. The prognosis for untreated uveitis is poor. Untreated anterior uveitis usually progresses to posterior uveitis, resulting in **cataracts**, scar tissue, and eventual glaucoma. If treated promptly, anterior uveitis usually clears up in several days or weeks, but is likely to recur. Posterior uveitis usually results in some permanent loss or blurring of vision.

Prevention

Patients with anterior uveitis should be warned about the possibility of recurrence and instructed about its symptoms, especially inflammation of the iris. They should be advised to seek treatment at once at the first signs of recurrence.

How vaccines work: A. Vaccines contain antigens (weakened or dead viruses, bacteria, and fungi that cause disease and infection). When introduced into the body, the antigens stimulate the immune system response by instructing B cells to produce antibodies with assistance from T-cells. B. The antibodies are produced to fight the weakened or dead viruses in the vaccine. C. The antibodies "practice" on the weakened viruses, preparing the immune system to destroy real and stronger viruses in the future. D. When new antigens enter the body, white blood cells called macrophages engulf them, process the information contained in the antigens, and send it to the T-cells so that an immune system response can be mobilized. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

- Adults over age 60: Shingles, (1 dose)
- Adults over age 65: Pneumococcal PPSV23 (1 dose)

Purpose

The first vaccine was developed in 1796 by English physician Edward Jenner who took a few drops of the fluid seeping from a pustule of a cowpox-infected woman and injected it into a healthy young boy. Six weeks later, Jenner injected the boy with fluid from a **smallpox** pustule, and the boy did not develop dreaded smallpox, a devastating disease that killed over a million people each year in Europe. By the start of the twentieth century, vaccines for smallpox, **rabies**, **diphtheria**, **typhoid fever**, and **plague** had been developed. Vaccines are available against more than 20 infectious diseases such as **influenza**, **pneumonia**, whooping **cough**, **rubella**, **meningitis**, **hepatitis B**, and **shingles**.

ALBERT BRUCE SABIN (1906–1993)

Albert Bruce Sabin was born on August 26, 1906, in Bialystok, Russia, to Jacob and Tillie Sabin. In order to escape extreme poverty, the Sabins immigrated to the United States and settled in Paterson, New Jersey. Following his graduation from high school in 1923, Albert Sabin was able to attend dentistry school at New York University due to his uncle's generous offer for financing. However, after reading Paul deKruif's *Microbe Hunters* he became intrigued by virology and the idea of curing epidemic diseases. After two years of dentistry school, Sabin decided to switch to medicine, earning his M.D. in 1931. Sabin completed his residency and internship in the United States and then went to London to conduct research.

Sabin returned to the United States in 1935 to resume his research of polio at the Rockefeller Institute. In 1953, Jonas Salk announced that he had created a dead-virus polio vaccine that was safe, but soon after its administration many people died. Sabin, however, wanted to create a live-virus vaccine, which he felt would be safer. Sabin diluted three strains of the polio virus and tested these on himself, his family, and other volunteers. These live-virus vaccines (given orally) proved safe and effective and soon became the vaccinations of choice around the world. Sabin's published works include *Viruses and Cancer: A Public Lecture in Conversational Style* (1965), *Behavior of Chimpanzee-Avirulent Poliomyelitis Viruses in Experimentally Infected Human Volunteers* (1955), and *Recent Advances in Our Knowledge of Dengue and Sand Fly Fever* (1955). Sabin died of congestive heart failure on March 3, 1993.

Vaccines are medicines that contain weakened or dead bacteria or viruses. When individuals are given a vaccine, their immune system responds by producing proteins called antibodies. When these persons are later exposed to live bacteria or viruses of the same kind that were in the vaccine, the antibodies destroy those organisms and prevent them from making these persons sick. Vaccines usually stimulate the cellular immune system as well. In other words, vaccinated individuals become immune to the disease that the organisms normally cause. The process of building up immunity by being given a vaccine is called immunization.

Vaccines are used in several ways. Some, such as the rabies vaccine, normally are given only when people are likely to have been exposed to the virus that causes the disease, for example, through a dog bite. Others are given to travelers planning to visit countries where certain diseases such as typhoid **fever** or **yellow fever** are common. Vaccines such as the influenza vaccine, also called a flu shot, are especially recommended for specific groups of people who are at high risk of developing influenza or its complications, although everyone is encouraged to get vaccinated against influenza. There are also vaccines that are given to almost everyone, such as the ones that prevent diphtheria, **tetanus**, **polio**, and **measles**.

Children in developed countries are routinely given a series of vaccinations that begin at birth. Given according to a specific schedule, these vaccinations protect against hepatitis B, diphtheria, tetanus, whooping cough, measles, **mumps**, rubella (German measles), varicella (**chickenpox**), polio, pneumococcus and *Haemophilus influenzae* type b (Hib disease, a major cause of spinal meningitis) and, in some U.S. states, **hepatitis A**. This series of vaccinations is recommended by the American Academy of Family Physicians, the American Academy of Pediatrics, and the Centers for Disease Control and Prevention (CDC). It is required in all U.S. states before children can enter school. All states will make exceptions for children who have medical conditions such as cancer that prevent them from having vaccinations, and some states also make exceptions for children whose parents object to vaccination for religious or other reasons.

Additional vaccines are available for preventing rotavirus infection (given to infants), **anthrax**, **cholera**, **Japanese encephalitis**, meningococcal meningitis, plague, **tuberculosis**, typhoid fever, and yellow fever.

Recommended dosage

The recommended dosage depends on the type of vaccine and may be different for different patients. Dosage is standardized for each specific type and usually varies based on recipient age. The healthcare professional who gives the vaccine determines the proper dose.

A vaccination health record helps parents and healthcare providers keep track of children's vaccinations. The record should be started when children have their first vaccination and should be updated with each additional vaccination. While most physicians follow the recommended vaccination schedule, parents should understand that some flexibility is allowed, for example, if children are sick at the time the vaccination is due. Slight departures will not prevent children from developing immunity, as long as all the vaccinations are given at approximately the right times. The physician is the best person to decide when each vaccination should be given.

Individuals who are planning a trip to another country should check to find out what vaccinations are needed. Some vaccinations must be given as much as 12 weeks before the trip, so getting this information

KEY TERMS

Anthrax—An infectious disease caused by a type of bacterium. The disease can be passed from animals to people and usually is fatal. Symptoms include sores on the skin.

Antibodies—Proteins that are normally produced by specialized white blood cells after stimulation by a foreign substance (antigen) and that act specifically against the antigen in an immune response.

Antigen—Any foreign substance, usually a protein, that stimulates the body's immune system to produce antibodies.

Bacteria—Tiny, single-celled forms of life that cause many diseases and infections.

Cholera—An infection of the small intestine caused by a type of bacterium. The disease is spread by drinking water or eating seafood or other foods that have been contaminated with the feces of infected people. It occurs in parts of Asia, Africa, Latin America, India, and the Middle East. Symptoms include watery diarrhea and exhaustion and are often fatal to young children and the elderly.

Cowpox—A mild disease in cows that is caused by a poxvirus.

Diphtheria—A serious, infectious disease that produces a toxin (poison) and an inflammation in the membrane lining of the throat, nose, trachea, and other tissues.

Encephalitis—Inflammation of the brain, usually caused by a virus. The inflammation may interfere with normal brain function and may cause seizures, sleepiness, confusion, personality changes, weakness in one or more parts of the body, and even coma.

Feces—The solid waste that is left after food is digested. Feces form in the intestines and pass out of the body through the anus. Also called stool.

Guillain-Barré syndrome (GBS)—A disease of the nerves with symptoms that include sudden numbness and weakness in the arms and legs, sometimes leading to paralysis. The disease is serious and requires medical treatment, but most people recover completely.

Immune system—The body's natural defenses against disease and infection.

Immunization—Administering a vaccine that stimulates the body to create antibodies to a specific disease (immunity) without causing symptoms of the disease.

Infectious disease—Any disease caused by invasion of a pathogen that subsequently grows and multiplies in the body.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

early is important. Many major hospitals and medical centers have travel clinics that can provide this information. The Traveler's Health Section of the Centers for Disease Control and Prevention also has information on vaccination requirements.

Precautions

Vaccines are not always 100% effective, and there is no way to predict whether a vaccine will fail to provide adequate immunity in any particular person. To be most effective in preventing disease outbreaks, vaccination programs depend on whole communities participating. The more people who are vaccinated, the lower everyone's risk of being exposed to a disease. Even people who do not develop immunity through vaccination are safer when their friends, neighbors, children, and coworkers are immunized. In addition to vaccines, hand washing and other forms of hygiene are the most effective means for preventing the spread of infectious diseases.

Like most medical procedures, vaccination has risks as well as substantial benefits. Individuals who receive vaccines should make sure they are fully informed about both the benefits and the risks. Any questions or concerns should be discussed with a physician or other healthcare provider. The Centers for Disease Control and Prevention (CDC) offers substantial information on immunizations and vaccinations.

In the early 2000s there was significant concern among some groups that vaccines may cause **autism**, based on a paper by Andrew Wakefield, a doctor in England. The paper was retracted after it was found that there were numerous methodological flaws as well as flaws in the conclusions that were drawn. Wakefield was subsequently stripped of his license and unable to practice medicine. Numerous follow-up studies by many well-respected groups found no link between vaccination and autism. Unfortunately, this concern led some parents to decide against vaccinating their

Influenza—A disease caused by viruses that infect the respiratory tract.

Measles—An acute and highly contagious viral disease that occurs primarily in children marked by distinct red spots followed by a rash.

Meningitis—Inflammation of tissues that surround the brain and spinal cord.

Microbe—A microorganism, especially a bacterium, that causes disease.

Mumps—An acute and highly contagious viral illness that usually occurs in childhood.

Pathogen—A disease-causing microorganism.

Plague—A highly infectious disease that can be fatal if not treated promptly. The bacteria that cause plague mainly infect rats, mice, squirrels, and other wild rodents. The disease is passed to people through fleas. Infected people can then spread the disease to other people.

Rabies—A rare but serious disease caused by a virus carried in saliva. It is transmitted to humans when an infected animal bites a person.

Rubella—A contagious viral disease that is milder than typical measles but is damaging to the fetus when it occurs early in pregnancy. Also called German measles.

Seizure—A sudden attack, spasm, or convulsion.

Smallpox—A highly contagious viral disease characterized by fever, weakness, and skin eruption with pustules that form scabs that slough off leaving scars.

Tuberculosis—An infectious disease that usually affects the lungs but may also affect other parts of the body. Symptoms include fever, weight loss, and coughing up blood.

Typhoid fever—An infectious disease caused by a type of bacterium. People with this disease have a lingering fever and feel depressed and exhausted. Diarrhea and rose-colored spots on the chest and abdomen are other symptoms. The disease is spread through poor sanitation.

Virus—A tiny, disease-causing particle that can reproduce only in living cells.

Whooping cough—An infectious disease, also called pertussis, especially of children that is caused by a bacterium and is marked by a convulsive, spasmodic cough, sometimes followed by a shrill intake of breath.

Yellow fever—An infectious disease caused by a virus. The disease, which is spread by mosquitoes, is most common in Central and South America and Central Africa. Symptoms include high fever, jaundice (yellow eyes and skin) and dark-colored vomit, a sign of internal bleeding. Yellow fever can be fatal.

children, which was blamed for subsequent outbreaks of what were once very rare diseases, such as measles.

Vaccines may cause problems for people with certain **allergies**. These individuals may have problems:

- People who are allergic to antibiotics neomycin or polymyxin B should not take rubella vaccine, measles vaccine, mumps vaccine, or the combined MMR vaccine.
- People who are allergic to baker's yeast should not take the hepatitis B vaccine.
- People who are allergic to antibiotics such as gentamicin sulfate, streptomycin sulfate, or other aminoglycosides should check with their physicians before taking influenza vaccine, as some influenza vaccines contain small amounts of these drugs.
- People who are allergic to eggs should not take vaccines grown in the fluids of chick embryos, including those for influenza, measles, and mumps.

In general, people who have had an unusual reaction to a vaccine in the past should inform their physician before taking the same kind of vaccine again. Their physician also should be told about any allergies to foods, medicines, preservatives, or other substances.

People with certain other medical conditions should be cautious about taking vaccines. Influenza vaccine, for example, may reactivate the rare Guillain-Barré syndrome (GBS) in people who have had it before. This vaccine also may worsen illnesses that involve the lungs, such as **bronchitis** or pneumonia. Vaccines that cause fever as a side effect may trigger seizures in people who have a history of seizures caused by fever.

Certain vaccines are not recommended for use during **pregnancy**, but some may be given to women at especially high risk of getting a specific disease such

WWW.BOOKBAZ.IR

as polio. Vaccines also may be given to pregnant women to prevent medical problems in their babies. For example, vaccinating a pregnant woman with tetanus toxoid can prevent her baby from getting tetanus at birth.

Women should avoid becoming pregnant for three months after taking rubella vaccine, measles vaccine, mumps vaccine, or the combined MMR as these vaccines could cause problems in the unborn baby.

Women who are **breastfeeding** should check with their physicians before taking any vaccine.

Side effects

Most side effects from vaccines are minor and easily treated. The most common are **pain**, redness, and swelling at the site of the injection. Some people may develop a fever or a rash. In rare cases, vaccines may cause severe allergic reactions, swelling of the brain, or seizures. Anyone who has an unusual reaction after receiving a vaccine should contact a physician immediately.

Interactions

Vaccines may interact with other medicines and medical treatments. When this happens, the effects of the vaccine or the other medicine may change or the risk of side effects may be greater. For example, **radiation therapy** and cancer drugs may reduce the effectiveness of many vaccines or may increase the chance of side effects. Individuals who plan to receive a vaccine should let the physician know all other medicines they are taking and should ask whether the possible interactions could interfere with the effects of the vaccine or the other medicines.

Vaginal pain

Definition

Pain in the vaginal canal is usually associated with an underlying medical and/or psychological condition.

Demographics

Approximately 50–85% of the causes of vaginal pain are due to organic (medical) conditions. However, it is typical for the medical condition to be compounded

KEY TERMS

Laparoscopic surgery—A surgical procedure to correct or diagnose an underlying disease.

by psychological issues such as depression, problems associated with sexual identity, or problems relating to personal female medical conditions (sometimes experienced by **breast cancer** and **hysterectomy** patients). The overall prevalence for vaginal pain experienced during sexual intercourse (**dyspareunia**), is 20% (15% of women and 57% of men).

Description

The vagina has three physiological functions: an outflow duct for menstrual discharge, to receive the penis during sexual intercourse, and as the birthing canal. Vaginal pain is experienced usually during vaginal manipulation or sexual intercourse. The primary entity concerns dyspareunia.

Causes and symptoms

Causes can be categorized as organic, due to a medical condition, and/or psychological difficulties. Medical conditions can include chronic diseases, minor ailments, breast cancer, and medications. Psychological cause can be related to physical or **sexual abuse**. **Pregnancy** and hormonal changes (decreased estrogen) have significant negative impact on sexual activity, desire, and satisfaction. Dyspareunia can be divided into three types of pain: superficial, vaginal, and deep. Superficial pain is associated with attempted penetration. This condition is usually caused by changes in anatomy, irritative condition, or **vaginismus**. Vaginal pain is associated with friction, indicating a problem with lubrication and/or arousal disorders. Deep pain is related to thrusting and is indicative of pelvic disease or an inability for **pelvic relaxation**.

Diagnosis

Diagnosis must be pursued with diligence and in a comprehensive manner. A careful history and **physical examination** is essential. Procedures that can be used include surgical investigation (**laparoscopy**) and treatment of the underlying cause(s).

Treatment

Treatment is directed at diagnosing the underlying condition, which can be medical and/or psychological cause(s). Treatment can include surgery, hormonal therapy (replacements), **psychotherapy**, and pain control protocols.

Prognosis

Prognosis depends on the primary cause. If treatment is aggressively pursued and patient compliance is satisfactory, the overall outcome is favorable.

Prevention

There are no precise preventive measures since the condition can result from normal **aging** and/or progressively worsening psychological disease.

Vaginismus

Definition

Vaginismus is a **sexual dysfunction** in which the muscles of the outer third of the vagina involuntarily contract or spasm during attempts at vaginal penetration, thereby closing the vagina.

Demographics

Sexual disorders are common among women, yet many cases go unreported and there is little accurate data regarding the incidence of specific problems. Vaginismus is believed to be uncommon. It is thought to occur most often in women of higher educational attainment and socioeconomic status.

WWW.BOOKBAZ.IR

Description

Vaginismus is a reflex response to pressing on the vagina. Women with vaginismus do not intentionally contract their vaginal muscles; rather the muscles of the outer vagina tighten automatically, often causing **pain**. Vaginismus can occur with any type of attempted vaginal penetration such as a penis, speculum, tampon, or other object. Sometimes it occurs with mere touching. Pushing harder increases the pain and most women with vaginismus cannot tolerate sexual intercourse. Vaginismus does not affect a woman's desire for sexual intercourse. Most women with vaginismus enjoy sexual activity that does not involve penetration and many have orgasms through clitoral stimulation.

There are different types of vaginismus:

- Lifelong vaginismus is the most common type and begins the first time vaginal penetration is attempted.
- Acquired vaginismus begins after a period of normal sexual functioning, often after a physical condition causes an episode of painful intercourse or after a woman has intercourse while emotionally distressed.
- General vaginismus occurs whenever vaginal penetration is attempted.
- Situational vaginismus occurs only in specific situations, such as with a certain sexual partner or during a gynecological examination.

Risk factors

Risk factors for vaginismus include physical conditions that cause painful intercourse, as well as sexual **trauma** or negative feelings about sex.

Causes and symptoms

There are many possible causes for vaginismus, but sometimes no cause can be determined. Vaginismus sometimes develops following painful intercourse caused by a physical condition. Such conditions include:

- infections of the vulva or vagina
- vulvodynia or vulvar vestibulitis, a stinging or burning around the opening to the vagina
- chronic pelvic pain from an underlying medical condition
- scars on the vagina from injury, childbirth, or surgery
- radiation therapy
- menopause or a medical treatment that affects female hormone levels
- irritation from douches, spermicides, or the latex in condoms

KEY TERMS

Cognitive behavioral therapy (CBT)—Psychotherapy that emphasizes the substitution of desirable patterns of thinking for undesirable patterns.

Coitus—Sexual intercourse.

Desensitization—The elimination of an emotional response, such as fear or anxiety, to specific stimuli.

Kegel exercises—Repetitive contractions to tone the pubococcygeal muscle of the pelvic floor for enhancing sexual response during intercourse or controlling incontinence.

Pelvic exam—A gynecological exam of the female reproductive organs.

Vulva—The external female genital organs, including the labia majora, labia minora, clitoris, and vestibule of the vagina.

Vulvar vestibulitis—A localized inflammation of the vestibule—the region immediately surrounding the opening of the vagina and the urethra.

Vulvodynia—A chronic burning, stinging, or irritation of the vulva.

There are also various psychological causes of vaginismus. A common cause of vaginismus is the belief that sex is wrong, sinful, or "dirty"—often resulting from parental or religious teachings. In addition, a painful first sexual experience can cause the body to react as if all sexual intercourse will be painful. A traumatic childhood experience, such as sexual molestation, may cause lifelong vaginismus, while acquired vaginismus often results from sexual assault or rape. Women who feel threatened or powerless in a relationship may subconsciously tighten their vaginal muscles in defense or silent defiance. Another cause is fear of becoming pregnant.

According to the psychiatric handbook, the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Editon-Text Revision (DSM-IV-TR)*, a diagnosis of vaginismus requires that the response is due to psychological factors or a combination of psychological and medical factors, but not to medical factors alone.

The major symptom of vaginismus is the severe contraction of the outer vaginal muscles as the vagina is about to be penetrated. This may completely prevent penetration or make it difficult and painful. Women with vaginismus may be unable to consciously relax their vaginal muscles even when they truly desire

to have sexual intercourse or allow penetration. Pelvic examinations may also be painful Some women cannot tolerate inserting a tampon or have never even tried.

Diagnosis

Examination

Diagnosing sexual disorders such as vaginismus is often very difficult, primarily due to discomfort or embarrassment about sexual discussions, even with a personal physician. Cultural norms and taboos often deter women from seeking help. Sometimes women are more comfortable consulting a physician if they are accompanied by a close friend or family member.

Involuntary spasm during a pelvic examination by a gynecologist or other women's healthcare specialist can confirm a diagnosis of vaginismus. The exam must be conducted as slowly and gently as possible. Physicians must explain what they are doing in detail. The woman may be offered a mirror and asked to guide the physician's hand or instruments into the vagina. Sometimes treatment for vaginismus must be initiated before a pelvic examination can be completed.

A complete physical exam and medical and sexual history are necessary to rule out other causes of painful sexual intercourse. The exam may reveal an infection, **scars**, or other abnormalities underlying the vaginismus. If physiological causes for the condition are ruled out, the patient may be referred to a psychiatrist, psychologist, or sex therapist.

According to the *DSM-IV-TR*, the first criteria for a diagnosis of vaginismus are that **muscle spasms** in the outer third of the vagina are involuntary and are recurring or persistent. The symptoms must cause physical and/or emotional distress or, in particular, problems with relationships. The symptoms must exist independently of another mental disorder that could account for them.

Treatment

As with most sexual disorders, there are many different treatments for vaginismus. Physical causes of vaginismus may require surgery or other treatment. Beyond that, treatment is aimed at reducing the **anxiety** and fear associated with penetration in order to weaken the reflexive tightening of vaginal muscles.

Desensitization techniques can, over time, enable a woman to relax her vaginal muscles and overcome the reflexive tightening of vaginismus. The woman begins by touching an area as close to her vaginal opening as possible without causing pain. Each day she touches a bit closer to the opening, becoming used to touching without pain. Once she can touch the tissues around the opening (the labia), she practices opening the vagina. Using a mirror to view her genitals, and bearing down, as if having a bowel movement, the opening is widened to make it more visible. Once she can touch the opening without pain, the woman inserts a finger past her hymen, pushing or bearing down to enlarge the opening. A small plastic dilator or cone is then inserted into the vagina, leaving it in place for 10–15 minutes. Once the vaginal muscles become used to the pressure, progressively larger inserts are used. Eventually, a dilator the size of a penis can be inserted comfortably. The woman's partner is then invited to insert the dilator. The couple then may attempt sexual intercourse. At first the woman may hold her partner's penis and insert it in her vagina. Some women are also more comfortable being on top during intercourse.

Desensitization procedures are somewhat controversial because they address the symptoms but not the cause of vaginismus. The exercises should be pursued under the direction of an experienced therapist or other healthcare provider. They should involve the sexual partner and gradually include intimate contact before culminating in sexual intercourse. Sometimes a male partner becomes overly cautious and reluctant to push and may lose his erection. In that case a phosphodiesterase inhibitor (sildenafil [Viagra], tadalafil [Cialis], or vardenafil [Levitra]) may be prescribed for the man.

Therapists also use **psychotherapy** or psychological techniques, couples or dual-sex therapy, **group therapy**, **hypnotherapy**, and/or behavioral therapies to treat vaginismus. Therapies should include information about sexual anatomy, **physiology**, the sexual response cycle, and common myths about sex. Treatment is usually extensive and multiple techniques are often used simultaneously.

Individual therapy often focuses on identifying and resolving underlying causes for vaginismus, such as childhood trauma or rape. When a woman has a trusting relationship with her therapist, insecurities or fears around sex resulting from factors such as parental attitudes or religious upbringing can often be revealed and successfully resolved.

Couples or dual-sex therapy is based on the concept that any sexual problems must be addressed by the couple, rather than the affected individual alone. The therapist will interact with the partners individually and as a couple. Addressing the couple's sexual

WWW.BOOKBAZ.IR

history and any relationship problems may help to reveal and resolve the causes of vaginismus, especially when the disorder represents a nonverbal form of protest within a relationship. The couple is educated about the condition and taught various activities that may be helpful in overcoming the disorder.

Group therapy also can be effective for treating vaginismus. Couples or individuals who have the same or similar sexual disorders are brought together in a group. This setting can provide comfort and support for women or couples who are embarrassed or ashamed about their problem. Witnessing others discussing sex and sexual problems in an open and honest forum can encourage patients to become more open and honest themselves. Group therapy also exerts a certain amount of positive pressure and encouragement to open up and express oneself and to follow through with "homework," which may include masturbation or certain kinds of foreplay.

Hypnotherapy is effective for some patients with vaginismus. Hypnotherapy tends to focus on overcoming the condition itself, rather than resolving any underlying causes or conflicts. It often entails a number of sessions during which the patient and therapist define the goals of hypnotherapy. When the actual hypnosis occurs, suggestions are aimed at resolving underlying fears or concerns and alleviating symptoms. For example, the patient may be told that she can have intercourse without pain and that she will be able to overcome her muscle spasms. Problems that are causing the vaginismus may be explored under hypnosis and attempts made to reverse underlying feelings or fears.

Cognitive behavioral therapy (CBT) assumes that vaginismus is a learned behavior that can be unlearned. Behavioral therapy usually involves desensitization. Patients are exposed to situations that create a mild sense of psychological discomfort or anxiety. Once this mild anxiety is overcome, they are exposed to sexual situations that they find successively more threatening, until eventually coitus is achieved without difficulty.

Drugs

Infections underlying vaginismus can be treated with medications. One study found that injections with botulinum neurotoxin type A was often effective in treating vaginismus in women with vulvar vestibulitis syndrome.

Alternatives

Biofeedback may help teach a woman to control her vaginal muscles.

Home remedies

Specific exercises, including pelvic floor muscle contractions and relaxation called Kegel exercises, may help women control muscle contractions during sex.

Prognosis

Vaginismus is one of the most treatable sexual disorders, with a success rate of at least 63%. Because the causes of vaginismus vary, different treatments are successful with different women. In general a treatment plan that combines two or more therapeutic techniques supervised by a specialist in **sex therapy** has the greatest likelihood of success. Untreated vaginismus can lead to unsatisfying sexual relationships, tension, and emotional distress between partners.

Prevention

There are no known preventions for vaginismus; however, maintaining open and honest communication within a sexual relationship may help prevent the disorder. Seeking prompt treatment if vaginismus does occur can minimize problems.

Vaginitis and vulvovaginitis

Definition

Vaginitis is an inflammation of the vagina most often caused by a bacterial, fungal, or parasitic infection. In young girls, this may include inflammation of the vulva and is referred to as vulvovaginitis

Description

Vulvovaginitis, vulvitis, and vaginitis are general terms that refer to the inflammation of the vagina and/or vulva (the external genital organs of a woman). These conditions can be caused by bacterial, fungal, or parasitic infections. These conditions can also be caused by low estrogen levels (called "atrophic vaginitis") or any type of allergic or irritation response from things such as spermicidal products, **condoms**, soaps, and bubble bath.

In general, vaginitis causes abnormal vaginal discharge, irritation, and **itching**. One of the most common reasons why women visit a doctor is a change in the usual vaginal discharge, which may vary during the menstrual cycle. It is normal for a woman to have a vaginal discharge, the amount and consistency of which varies during the course of the menstrual cycle. Vulvovaginitis is the most common gynecological problem encountered by girls prior to **puberty** and the onset of menstruation.

Demographics

Bacterial vaginosis is the most common cause of vaginitis during the childbearing years. Forty percent to 50% of vaginitis cases are caused by bacterial vaginosis. The occurrence of bacterial vaginosis is difficult to determine but studies have proposed that 10–41% of women have had it at least once. The occurrence of bacterial vaginosis in the United States is highest among African-American women and women who have had multiple sexual partners, and lowest among Asian women and women with no history of sexual contact with men. Bacterial vaginosis is not considered a sexually transmitted disease although it can be acquired by sexual intercourse.

Bacterial vaginosis is not caused by a particular organism but is a change in the balance of normal vaginal bacteria. Ninety percent of the bacteria found in a healthy vagina belong to the *Lactobacillus* family. For unknown reasons, sometimes there is a shift in the bacterial population that results in overgrowth of other bacteria. Patients suffering from bacterial vaginosis have very high numbers of such bacteria as *Gardnerella vaginalis*, *Mycoplasmahominis*, *Bacteroides* species, and *Mobiluncus* species. These bacteria can be found at numbers 100 to 1,000 times greater than found in the healthy vagina. In contrast, *Lactobacillus* bacteria are in very low numbers or completely absent from the vagina of women with bacterial vaginosis.

Candida vulvovaginitis also has been called "vulvovaginal candidiasis," "candidal vaginitis," "monilial infection," or "vaginal yeast infection." About 20% to 25% of the vaginitis cases are *Candida* vulvovaginitis. It has been estimated that about 75% of all women get a vaginal yeast infection at least once. In 80–90% of the cases, *Candida* vulvovaginitis is caused by an overgrowth of the yeast *Candida albicans*. The remaining cases are caused by other species of *Candida*. It is not always known what causes the yeast overgrowth. However, **antibiotics** taken for any reason can inadvertently kill normal bacteria in the vagina and cause an overgrowth of *Candida*.

Candida vulvovaginitis is not considered a sexually transmitted disease because *Candida* species are commonly found in the healthy vagina, but it is a rare disease among celibate women, as well as girls before puberty. Vaginal yeast infections tend to occur more frequently in women who are pregnant, in women who are diabetic and not controlling their disease; or in women who are taking birth control pills or antibiotics. The **stress** of military deployment has also been found to be a factor in triggering vaginal yeast infections. Some women have four or more attacks per year, a condition called "recurrent vaginal candidiasis."

Trichomoniasis, which is sometimes called "trich," accounts for 15–20% of the cases of vulvovaginitis. It is estimated that about 2.3 million (3.1%) of American women get trichomoniasis each year, and as many as

WWW.BOOKBAZ.IR

120 million women worldwide. Unlike the other two causes of vulvovaginitis, trichomoniasis is a sexually transmitted disease. This means that the disease is passed from person to person only by sexual contact. Trichomoniasis occurs in both men and women and is caused by infection with the single-celled parasite *Trichomonas vaginalis*. Infection with *Trichomonas vaginalis* is frequently associated with other sexually transmitted diseases and assists the spread of the **AIDS** virus.

Causes and symptoms

Vulvovaginitis is most often caused by a bacterial, fungal, or parasitic infection as described above. Other microorganisms may cause vulvovaginitis, or it may be caused by allergic reaction, irritation, injury, low estrogen levels, and certain diseases. Risk factors for bacterial vaginosis include using an **intrauterine device** (IUD), non-white race, prior **pregnancy**, first sexual activity at an early age, having multiple sexual partners, and having a history of sexually transmitted diseases. Persons at an increased risk for *Candida* vulvovaginitis include those who have had previous candida infections, frequent sexual intercourse, use birth control pills, have AIDS, are pregnant, are taking antibiotics or **corticosteroids**, are diabetic, use douches, use perfumed feminine hygiene sprays, wear tight clothing, or use vaginal sponges or an IUD.

The typical symptoms of vaginitis are: vaginal discharge, itching, and irritation. Vulvovaginitis involves the vulva as well. Women may have few or no symptoms, while others may have pronounced symptoms. The main symptom of bacterial vaginosis is a fishy-smelling, thin, milky-white or gray vaginal discharge but itching and burning may also be present. The fishy smell is stronger after sexual intercourse. The symptoms of candida vulvovaginitis are itching, soreness, painful sexual intercourse, and a thick, curdy, white (like cottage cheese) vaginal discharge. Trichomoniasis symptoms are: painful urination, painful sexual intercourse, and a yellow-green to gray, foul smelling, sometimes frothy, vaginal discharge.

Diagnosis

Women who think that they have vulvovaginitis should always visit their doctor to get an accurate diagnosis. Many women assume that they have a yeast infection and take over-the-counter medicines without first consulting their doctors. Vulvovaginitis can be diagnosed and treated by a nurse practitioner or physician. Most insurance companies cover the costs of diagnosis and treatment. To diagnose vulvovaginitis, the doctor will examine the vagina (using a speculum to keep the vagina open) and take a sample of the vaginal discharge for tests and microscopic analysis. The microscopic examination of the vaginal discharge may be immediately performed in the doctor's office but laboratory culture results should be available in two to three days. Diagnosis may be difficult because there are many different causes of vulvovaginitis.

There are four signs that indicate that a woman has bacterial vaginosis. These signs (known as Amsel's criteria) are: a thin, milky white discharge that clings to the walls of the vagina, presence of a fishy odor, a vaginal pH greater than 4.5, and the presence of clue cells in the vagina. Clue cells are vaginal cells that are covered with small bacteria as seen under the microscope. A diagnosis of candida vulvovaginitis is made after finding a normal vaginal pH (4 to 4.5) and the presence of many yeast cells in the sample of vaginal discharge or growth of yeast on laboratory media. In the spring of 2004, the U.S. Food and Drug Administration (FDA) cleared a new quick test to diagnose trichnomonas infection. The test provides results in 10 minutes. The company that manufactures the test also has a rapid result test to bacterial vaginosis. A trichomoniasis diagnosis is made when the parasites are found in the vaginal discharge either by microscopic examination or in laboratory cultures.

Treatment

Both bacterial vaginosis and trichomoniasis require prescription medication for treatment. Candida vulvovaginitis may be treated with either prescription or over-the-counter medicines. It is not advisable to take over-the-counter vaginal yeast infection medicines if one does not have a yeast infection. An Institute of Epidemiological Research survey of 390 gynecologists found that 44% of the women who were diagnosed with bacterial vaginosis had first treated themselves with over-the-counter yeast infection medications.

Bacterial vaginosis should be treated daily for one week with the antibiotics metronidazole (Flagyl, Protostat) or clindamycin (Cleocin) either as pills taken orally or in a gel or cream form put into the vagina. Trichomoniasis is treated with either a large, single dose of metronidazole or with a smaller dose taken twice daily for one week. Male sexual partners of women with trichomoniasis also must be treated.

Candida vulvovaginitis is most often treated by the application of medicated gels, creams, or suppositories

applied directly to the vagina. The antifungal drugs used to treat candida vulvovaginitis include oral fluconazole (Diflucan), butoconazole (Femstat), clotrimazole (Gyne-lotrimin, Mycelex), miconazole (Monistat), and ticonazole (Vagistat). Most require only one or a few days of therapy to be effective. Women who have recurrent *Candida* infections may receive treatment for several weeks and then some form of a long-term preventive treatment. For atrophic vaginitis, especially in menopausal women, topical application of estrogen as a cream or in other forms can help with symptoms caused by thinning of the tissue lining the vagina.

Alternatives

One of the primary focuses of alternative treatment for vaginal conditions including vulvovaginitis is rebalancing the normal vaginal flora. To assist with this rebalancing, *Lactobacillus acidophilus* and *L. bifidus* are recommended, either taken internally or introduced directly into the vagina. Garlic (*Allium sativum*), both taken internally and inserted into the vagina (a peeled whole clove wrapped in gauze), may be helpful due to its antibacterial and antifungal actions. A variety of other herbs can be used as douches or in suppository form to help treat acute flare-ups of vaginal symptoms. For example a douche made by steeping 1–2 tsp of calendula (*Calendula officinalis*) in boiling water (let the water cool before using) may help reduce inflammation. A boric acid douche can help to acidify the vaginal pH so that unwanted bacteria cannot survive and multiply.

Dietary modification and nutritional supplementation may also be helpful in the treatment of vulvovaginitis. Antioxidant **vitamins**, including A, C, and E, as well as B complex vitamins, and **vitamin D**, are recommended. Foods to avoid include cheese, alcohol, chocolate, soy sauce, sugar, vinegar, fruits, and any fermented foods. Wearing cotton underwear, loose fitting clothes, and avoiding panty hose can help keep the vagina cool and dry, thus helping to prevent some forms of vulvovaginitis. Cases of chronic vulvovaginitis should be addressed by a gynecologist.

Prognosis

Vulvovaginitis is a disease with minor symptoms and most women respond well to medications. It is believed that certain vaginal infections, if left untreated, can lead to more serious conditions, such as **pelvic inflammatory disease**, endometritis, postsurgical infections, and spread of the AIDS virus.

Prevention

Vaginal infections may be prevented by following these suggestions:

- Over-the-counter yeast infection treatments should not be taken unless the woman had been diagnosed with candidiasis before and recognizes the symptoms.
- Douching should be avoided because it may disturb the balance of organisms in the vagina and may spread them higher into the reproductive system.
- Thoroughly dry oneself after bathing and remove a wet bathing suit promptly.
- Avoid wearing tight clothing and wear cotton underwear.
- Clean diaphragms, cervical caps, and spermicide applicators after use. Use condoms to avoid sexually transmitted disease.
- After a bowel movement, wipe from front to back to avoid spreading intestinal bacteria to the vagina.

KEY TERMS

Duodenum—The section of the small intestine closest to the stomach.

Gastric glands—Branched tubular glands located in the stomach.

Gastric ulcer—An ulcer of the stomach, duodenum, or other part of the gastrointestinal system. Also called a peptic ulcer.

Latarjet's nerve—Terminal branch of the anterior vagal trunk, which runs along the lesser curvature of the stomach.

Parietal cells—Cells of the gastric glands that secrete hydrochloric acid and intrinsic factor.

Peristalsis—The rhythmic contractions that move material through the bowel.

Pyloroplasty—Widening of the pyloric canal and any adjacent duodenal structure by means of a longitudinal incision.

Vagotomy

Definition

Vagotomy is the surgical cutting of the vagus nerve to reduce acid secretion in the stomach.

Purpose

The vagus nerve trunk splits into branches that go to different parts of the stomach. Stimulation from these branches causes the stomach to produce acid. Too much stomach acid leads to **ulcers** that may eventually bleed and create an emergency situation.

A vagotomy is performed when acid production in the stomach cannot be reduced by other means. The purpose of the procedure is to disable the acid-producing capacity of the stomach. It is used when ulcers in the stomach and duodenum do not respond to medication and changes in diet. It is an appropriate surgery when there are ulcer complications, such as obstruction of digestive flow, bleeding, or perforation. The frequency with which elective vagotomy is performed has decreased in the past 20 years as it has become clear that the primary cause of ulcers is an infection by a bacterium called *Helicobacter pylori*. Drugs have become increasingly effective in treating ulcers. However, the number of vagotomies performed in emergency situations has remained about the same.

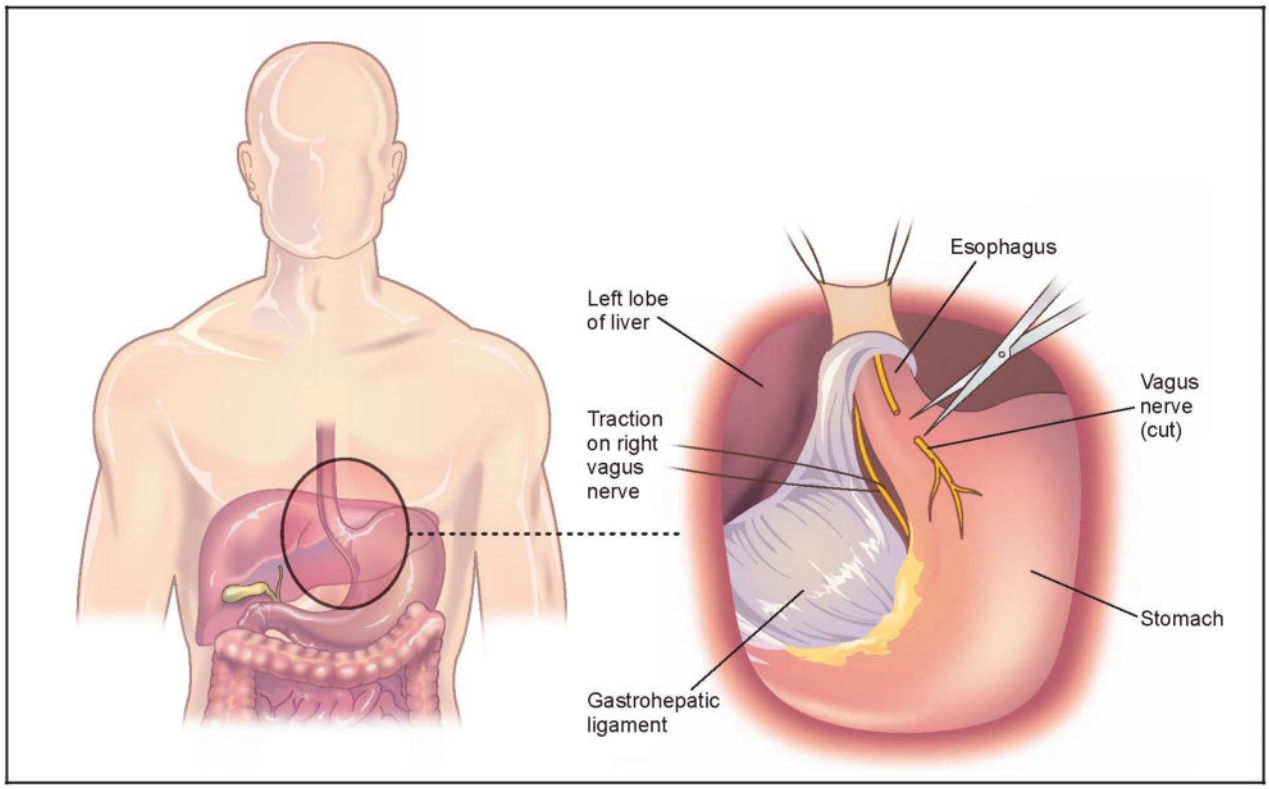
A vagotomy procedure is often performed in conjunction with another gastrointestinal surgery, such as partial removal of the stomach (antrectomy or subtotal **gastrectomy**).

Demographics

Gastric (peptic) ulcers are included under the general heading of gastrointestinal (GI) diseases. GI disorders affect an estimated 25%–30% of the world's population. In the United States, 60 million adults experience gastrointestinal reflux at least once a month, and 25 million adults suffer daily from **heartburn**. Left untreated, these conditions often evolve into ulcers. Four million people have active peptic ulcers; about 350,000 new cases are diagnosed each year. Four times as many duodenal ulcers as gastric ulcers are diagnosed. The first-degree relatives of patients with duodenal ulcer have a two to three times greater risk of developing duodenal ulcer. Relatives of gastric ulcer patients have a similarly increased risk of developing a gastric ulcer.

Description

Patients who receive vagotomies are most often seen in emergency situations where bleeding and perforated ulcers require immediate intervention. A vagotomy is usually performed by a board-certified surgeon, either a general surgeon who specializes in gastrointestinal



To perform a vagotomy, the surgeon makes an incision in the patient's abdomen. Once the stomach is located, the vagus nerves are cut. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

surgery or a gastrointestinal endoscopic surgeon. The procedure is performed in a hospital setting.

A vagotomy can be performed using closed (laparoscopic) or open surgical techniques. The indications for a laparoscopic vagotomy are the same as for open vagotomy.

There are four basic types of vagotomy procedures:

- In truncal or total abdominal vagotomy, the main vagal trunks are divided, and surgery is accompanied by a drainage procedure, such as pyloroplasty.
- With selective (total gastric) vagotomy, the main vagal trunks are dissected to the point where the branch leading to the biliary tree divides, and there is a cut at the section of vagus close to the hepatic branch. This procedure is rarely indicated or performed.
- Highly selective vagotomy (HSV) selectively deprives the parietal cells of vagal nerves and reduces their sensitivity to stimulation and the release of acid. It does not require a drainage procedure. The branches of Latarjet's nerve are divided from the esophagogastric junction to the crow's foot along the lesser curvature of the stomach.
- Thoracoscopic vagotomy is performed through the third, sixth, and seventh left intercostal spaces. The posterior vagus trunk is isolated, clipped, and a segment excised.

A vagotomy is performed under general **anesthesia**. The surgeon makes an incision in the abdomen and locates the vagus nerve. Either the trunk or the branches leading to the stomach are cut. The abdominal muscles are sewn back together, and the skin is closed with sutures.

Often, other gastrointestinal surgery is performed (e.g., part of the stomach may be removed) at the same time. Vagotomy causes a decrease in peristalsis, and a change in the emptying patterns of the stomach. To ease this, a **pyloroplasty** is often performed to widen the outlet from the stomach to the small intestine.

Preparation

A gastroscopy and x rays of the gastrointestinal system determine the position and condition of the ulcer. Standard preoperative blood and urine tests are done. The patient discusses with the anesthesiologist any medications or conditions that might affect the administration of anesthesia.

WWW.BOOKBAZ.IR

Aftercare

Patients who have had a vagotomy stay in the hospital for about seven days. Nasogastric suctioning is required for the first three or four days. A tube is inserted through the nose and into the stomach. The stomach contents are then suctioned out. Patients eat a clear liquid diet until the gastrointestinal tract regains function. When patients return to a regular diet, spicy and acidic foods should be avoided.

It takes about six weeks to fully recover from the surgery. The sutures that close the skin can be removed in seven to ten days. Patients are encouraged to move around soon after the operation to prevent the formation of deep vein **blood clots**. **Pain** medication, stool softeners, and **antibiotics** may be prescribed following the operation.

Risks

Standard surgical risks, such as excessive bleeding and infection, are potential complications. In addition, the emptying patterns of the stomach are changed. This can lead to dumping syndrome and **diarrhea**. Dumping syndrome is a condition in which the patient experiences **palpitations**, sweating, nausea, cramps, **vomiting**, and diarrhea shortly after eating.

The following complications are also associated with vagotomy surgery:

- Gastric or esophageal perforation may occur from an electrocautery injury or by clipping the branch of the nerve of Latarjet.
- Delayed gastric emptying is most common after truncal or selective vagotomy, particularly if a drainage procedure is not performed.

People who use alcohol excessively, smoke, are obese, and are very young or very old are at higher risk for complications.

Results

Normal recovery is expected for most patients. Ulcers recur in about 10% of those who have a vagotomy without stomach removal. Recurrent ulcers are also found in 2%–3% of patients who have some portion of their stomach removed.

Morbidity and mortality rates

In the United States, approximately 3,000 deaths per year are due to duodenal ulcers and 3,000 to gastric ulcers. There has been a marked decrease in reported hospitalization and mortality rates for gastric ulcers.

Alternatives

The preferred short-term treatment for gastric ulcers is drug therapy. A review surveying medical articles published from 1977 to 1994 concluded that drugs such as cimetidine, ranitidine, famotidine, H2 blockers, and sucralfate were efficient, with omeprazole considered the "gold standard" for active gastric ulcer treatment. Surgical intervention, however, is recommended for people who do not respond to medical therapy.

Valsalva maneuver

Definition

The Valsalva maneuver is performed by attempting to forcibly exhale while keeping the mouth and nose closed. It is used as a diagnostic tool to evaluate the condition of the heart and is sometimes done as a treatment to correct abnormal heart rhythms or relieve chest **pain**.

Purpose

The Valsalva maneuver is used with patients who have suspected heart abnormalities, often in conjunction with **echocardiography**. The maneuver is based on the fact that when a patient forcibly exhales against a closed nose and mouth while bearing down, as if having a bowel movement, specific changes occur in blood pressure and the rate and volume of blood returning to the heart.

Comparing the changes in a diseased heart to those expected in a normal heart gives clues to the type and location of heart damage. In addition, when a doctor listens to the chest with a stethoscope during the Valsalva maneuver, characteristic heart sounds are heard. Variations in these sounds can indicate the type of abnormality present in the heart. A 2004 study found that blood pressure response to the Valsalva maneuver could predict mortality in elderly patients with **congestive heart failure**. This could prove to be a new noninvasive way to help determine how long elderly patients with congestive **heart failure** are expected to live.

The Valsalva maneuver also corrects some rapid heartbeats originating in the atria. When the maneuver is done correctly, blood pressure rises. This forces the heart to respond by correcting its rhythm and beating more slowly. On rare occasions, the Valsalva maneuver can be used to diminish chest pain in patients with mild coronary disease.

Unrelated to any evaluation of the heart, the Valsalva maneuver also is taught to patients with **multiple sclerosis** who are unable to fully empty the bladder (flaccid bladder). It sometimes is used in sexual therapy to help men avoid **premature ejaculation**.

Precautions

The Valsalva maneuver should not be performed by patients who have severe **coronary artery disease**, have experienced recent **heart attack**, or have a moderate to severe reduction in blood volume.

KEY TERMS

Atria—Two sections of the heart that take in blood from the veins.

Echocardiography—An ultrasound test that shows the size, shape, and movement of the heart.

Description

When performed formally, the patient is asked to blow against an aneroid pressure measuring device (manometer) and maintain a pressure of 40 millimeters of mercury (mm Hg) for 30 seconds. Less formally, the patient may be asked to bear down, as if having a bowel movement. During this 30 second period, a recording is made of the changes in blood pressure and murmurs of the heart.

Preparation

The patient may be connected to a heart monitor and echocardiograph or the physician may simply use a stethoscope to monitor the heart. Sometimes an indwelling needle is inserted for accurate pressure measurements, depending on whether the procedure is being done for corrective or diagnostic purposes.

Aftercare

When this procedure is done to regulate irregular heart rhythms, the patient usually remains on a heart monitor to evaluate heartbeat.

Risks

The patient may feel dizzy or faint during the procedure, but serious consequences are rare. There is a risk that the Valsalva maneuver can cause **blood clots** to detach, bleeding, and abnormal rhythms originating in the ventricle. It can also cause cardiac arrest. Consequently, the procedure is usually performed in a setting where emergency equipment is accessible.

Results

There are four characteristic changes or phases in a normal heart's response to the Valsalva maneuver. An abnormality in any of these phases indicates a cardiovascular abnormality.

Valvular heart disease

Definition

Valvular **heart disease**, sometimes also called heart valve disease, refers to several disorders and diseases of the heart valves, which are the tissue flaps that regulate the flow of blood through the chambers of the heart. In other words, one of the valves of the heart does not work properly. Any one of the four heart valves—the aortic, mitral, pulmonary, and tricuspid—may become damaged or have a defect. When this occurs, valvular heart disease is used to describe the medical condition. Further, multivalvular heart disease refers to a condition involving problems with more than one of the heart valves, although valvular heart disease is also used when describing problems with more than one heart valve.

Description

The human heart consists of four chambers—two upper chambers (the atria) and two lower chambers (the ventricles)—that are responsible for pumping blood. The heart valves, which are located at the exit of each of the four chambers of the heart, are like one-way doors, which open and close with each beat of the heart, controlling the blood flow from one chamber to the next. Each of these valves consists of a few thin folds of tissue. When functioning correctly, they allow the blood to flow with a proper force, in a proper direction, and at a proper time. With respect to direction, proper functioning valves keep blood from flowing backward into a chamber when closed; that is, blood always flows forward. However, when valvular heart disease occurs, a valve becomes hardened and/or narrowed so it cannot open fully or cannot close completely, which allows blood to leak backward.

The four valves function in the following manner:

- The aortic valve is located on the left side of the heart and opens to allow blood to leave the heart from the left ventricle into the aorta, which is the main artery of the body. It closes to prevent blood from flowing back into the left ventricle.
- The mitral valve is located between the left atrium and the left ventricle. It is the only valve with two flaps, or cusps.
- The pulmonary valve is situated on the right side of the heart, between the right ventricle and pulmonary artery. It allows blood to exit the heart and enter the lungs via the pulmonary artery. It closes to prevent blood from flowing back into the right ventricle.
- The tricuspid valve is located on the right side of the heart, between the right atrium and right ventricle. It is made up of three cusps, each a different size.

The aortic and mitral valves are the two valves most often affected by valvular heart disease.

Patients with valvular heart disease have a malfunction of one or more of these valves. There are several types of valvular heart disease with distinct symptoms and treatments. These are:

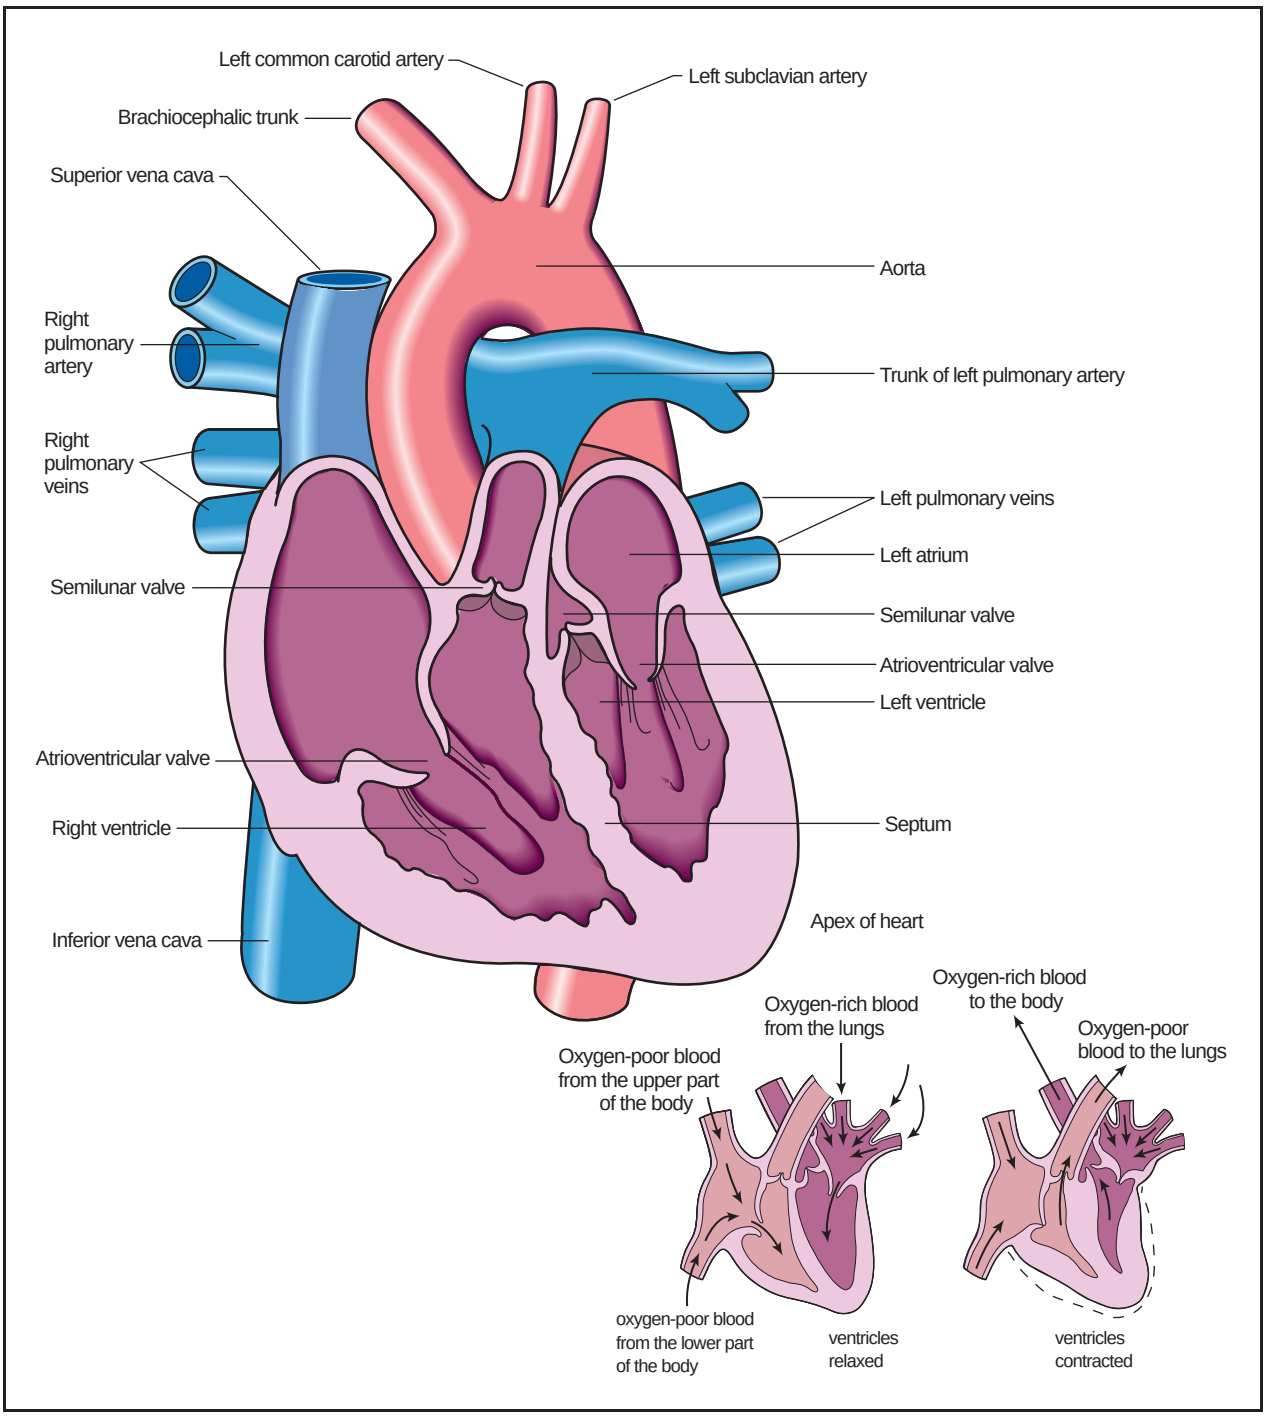
- mitral valve prolapse (displacement)
- mitral valve insufficiency (regurgitation)
- mitral valve stenosis (narrowing)
- aortic valve insufficiency
- aortic valve stenosis
- tricuspid valve insufficiency
- tricuspid valve stenosis
- pulmonic stenosis
- pulmonic insufficiency

Certain types of heart disease can lead to one of the specific conditions listed above. These include **rheumatic fever** and infective inflammation of the heart (**endocarditis**).

Demographics

According to the American Heart Association, as of 2013, approximately five million Americans are diagnosed with valvular heart disease in any given year. However, that number was expected to drastically rise in the near future as the country's population continued to age. Specifically, it was projected that valvular heart disease would increase from 6.9 million in 1990 to about 25 million in the year 2050. As of 2013, the prevalence of moderate to severe valvular heart disease stands at over one in eight Americans of 75 years of age or older.

The 2011 paper "Valvular Heart Disease: The Next Cardiac Epidemic," which was published in the journal *Heart,* stated: "The epidemiology of valvular heart disease (VHD) has changed dramatically over the past 50 years in developed nations. While rheumatic disease is now uncommon, a steady rise in life expectancy has been accompanied by a progressively increasing frequency of degenerative valve disease."



Anatomy of the human heart. The illustration at the bottom right shows how the right and left ventricles contract and relax when blood is pumped through the heart. *(Illustration by Hans & Cassady, Inc.© Cengage Learning®.)*

The authors of the paper added, "Although an accurate overall picture of the epidemiology of VHD has yet to be established, the overall prevalence in the USA is 2.5% with wide age-related variation from 0.7% in those aged 18–44 years to 13.3% in those over the age of 75." They contend, based on international population statistics, that a significant increase in morbidity and mortality will result from VHD due to a continuing increase in the world's elderly population. In the United Kingdom, for instance, the population of those aged 85 years and olded is set to double by 2028. With that doubling, a related increase in the

WWW.BOOKBAZ.IR

number of cases of valvular heart disease is also predicted to occur.

Causes and symptoms

Problems with heart valves may occur as a result of infection, degeneration, or congenital abnormality. Symptoms may vary with severity, with mild cases having few or no symptoms and serious cases having many symptoms, such as those associated with **congestive heart failure**. Some of the general symptoms associated with valvular heart disease are the same symptoms found with congestive **heart failure**. These are:

- shortness of breath or difficulty catching one's breath
- wheezing after limited exertion
- swelling of the hands, abdomen, ankles, or feet
- palpitations (rapid heart rhythm, irregular heartbeat, or skipped beats)
- chest pain or discomfort
- dizziness or weakness
- fainting
- fever
- rapid weight gain (as much as two or three pounds per day)

Some of the different causes of valvular heart disease include:

- Age. Tissue of the heart valves may degenerate as one ages.
- Bacterial endocarditis. An infection affects the inner lining of the heart muscle and valves.
- High blood pressure. Heightened blood pressure can damage the aortic valve.
- Atherosclerosis. Hardening of arteries may damage the aortic valve.
- Heart attack. Heart attacks can damage the muscles that control the valves of the heart.
- Some drugs. Methyserigide, a medicine used to treat migraine headaches, some diet drugs, and other drugs can cause heart disease.
- Radiation therapy. Radiation used to treat cancer can cause valvular heart disease.

The most common infections that cause valvular heart disease are rheumatic **fever** and infective endocarditis.

Rheumatic fever

Rheumatic fever is a condition that results from the body's immune response to certain types of streptococcal bacteria. It occurs rarely. When it occurs, it is most often in children who have had **strep throat** that was not completely treated. The symptoms of rheumatic fever include heart inflammation, uncontrolled movement of face and limbs, arthritis that moves from joint to joint, **shortness of breath**, weakness, and either lumps under the skin or raised red patches on the skin. The most common valvular heart diseases to result from rheumatic fever are mitral stenosis, tricuspid stenosis, aortic insufficiency, aortic stenosis, multivalvular involvement, and less commonly, pulmonic stenosis. Chronic rheumatic heart disease can result from one occurrence or from repeated attacks. It is not as common as it once was in the United States but still occurs frequently in developing countries.

Infective endocarditis

Infective endocarditis is an infection and inflammation of the inner layer, or membrane, of heart tissue (endocardium). Most people with a healthy, normal heart are not at significant risk for contracting infective endocarditis. However, people who have had rheumatic fever, with its resulting scarring, or a congenital cause of heart malformation, may contract this disease when certain bacteria enter the bloodstream and become lodged in the heart. In particular, dental surgery or any surgery involving the mouth, bladder, prostate, or female pelvic organs increases risk for this infection. The disease also may occur in drug addicts who inject their veins using unsterilized needles, even if they have normal heart valves. Symptoms of infective endocarditis include fever, a new or changing heart murmur, and abnormal loss of appetite or **fatigue**.

The use of appetite suppressants
